BY COURTESY OF THE CONSULATE GENERAL OF CANADA
SMELTER AND SURFACE BUILDINGS OF GASPÉ COPPER MINE DEVELOPED IN THE 1950S TO EXPLOIT MURDOCKVILLE DEPOSITS

Agriculture.—The concentration of the population in the southern part of the province developed historically in response to the possibilities for agriculture afforded by the fine level soils of the lowlands and the undulating moraine-covered plateaus of the Appalachian region. The lowlands are used largely for animal feed, principally hay, for dairy cattle. Tobacco is grown on the sandy soils of the Joliette area, vegetables in the area of muck soil south of Montreal, and apples on the slopes of the Monteregian hills. The Townships are another dairying area, but there only half the land is cleared, while forest products include maple sugar. In the Gaspé peninsula, only a narrow coastal fringe is cultivated, and supplementary income is provided by lumbering or fishing. The clay belt of western Quebec and the Lake St. John depression provide the only agriculture in the shield region.

Although less than 4% of the total land area of Quebec is farmland, agriculture was the mainstay of the economy until the outset of World War I, accounting for about 60% of total production in the province. Thereafter farming became more mechanized, culminating in the "agricultural revolution" beginning during World War II and continuing afterward. Farm production per acre and per worker increased but industrialization outstripped agriculture to the extent that in the 1960s it accounted for less than 10% of the net value of production in the province. The main products are wheat, oats, barley, rye, peas, beans, buckwheat, potatoes, turnips, hay, clover, alfalfa, corn fodder and sugar beets.

Forestry.—More than two-thirds of the total area of the province is forested and much of this is productive. The greater part of the forest area remains in the hands of the crown, some is privately owned. Varieties include spruce, balsam fir, white pine, red pine, jack pine, hemlock, cedar (white and red), tamarack, birch, maple, basswood, elm, ash, white birch, aspen, poplar, oak (white, red, burr), butternut, cherry, beech, walnut and hickory.

Furs and Fisheries.—Trapping is still important in Ungava and fur farming is fairly popular in some districts. Mink easily ranks first in production. Other species include fox and bear, beaver, ermine, fisher, lynx, marten, muskrat, otter, raccoon and skunk. The maritime fisheries are important in the Gaspé peninsula, the north shore and the Magdalen Islands. The principal species are cod (more than half the value of the catch), mackerel, lobster, herring, smelt and eel.

Industry.—Industrial development is based largely upon the power of the rivers descending the steep southern margin of the shield, and of other streams, including the St. Lawrence itself. Quebec produces more electric power than any other province in Canada and is richest in available water resources. In the second half of the 20th century the total installed water power capacity was more than 12,000,000 h.p., or almost 50% of the Canadian total. The forest and mineral resources of the province and the presence of the navigable channel of the St. Lawrence have been important contributory factors. The most important industrial centre of the province is Montreal. The shield edge is marked by a chain of industrial towns at power sites, including Hull, near the mouth of the Gatineau river, Shawinigan and other towns on the St. Maurice river, and Arvida near the large Shipshaw plant and other centres on the Saguenay river. There are sawmills, pulp and paper mills, and aluminum smelters. More pulp mills use the forest resources at scattered power sites in the Eastern Townships, the "New England of Canada." Towns like Granby and Sherbrooke produce a variety of manufactured goods. Magog concentrates on cotton textiles. Other leading industries in Quebec include men's factory clothing; railway rolling-stock; shipbuilding and repairs; aircraft and parts; acids, alkalies and salts; brass and copper products; miscellaneous chemical products; and furniture. Industries that are smaller but nevertheless represent a substantial part of total Canadian production include leather footwear and medicinal and pharmaceutical preparations.

Mining.—In mineral production, Quebec ranks second to Ontario, accounting for about 20% of the \$2,500,000,000 value of Canadian minerals mined annually. Apart from the asbestos mined in the Eastern Townships, as at Thetford Mines, most of Quebec's minerals are obtained from the Precambrian rocks of the shield. The oldest established mining centres are in western Quebec in the Noranda area, which like the more recently developed Chibougamau area to the east, produces gold, copper and zinc. Newer mining areas are being developed in the eastern part of the shield, together with the power potential of the southward-flowing rivers. The most northerly of new mining towns is the iron mining centre, Schefferville (see LABRADOR-UNGAVA: *Economy*; see also CANADA: *The Economy: Mining and Minerals*).

Transportation and Communication.—The St. Lawrence

BY COURTESY OF THE CONSULATE GENERAL OF CANADA

ST. LAMBERT LOCK, PART OF THE ST. LAWRENCE SEAWAY, WITH THE CITY OF MONTREAL, A MAJOR PORT AND THE INDUSTRIAL CENTRE OF THE PROVINCE, IN THE BACKGROUND

seaway furnishes deepwater communication to Quebec's main ports. Montreal is one of the most important rail-water-air connecting points in North America. In addition it leads the province in manufacturing and vies with Toronto in Ontario in banking and finance.

The province has railway lines of the Canadian National and Canadian Pacific railways, as well as pulp and paper company lines, together with about 50 mi. (80 km.) of New York Central feeder line into Montreal. In the 1950s a 360-mi. (579-km.) railway was built at Seven Islands (Sept-Îles) to run to the iron-ore deposits adjacent to the Labrador boundary. Montreal and Quebec city are major ocean ports used regularly by Canadian and foreign shipping lines.

(M. K. O.)

QUEBEC, the oldest city of Canada and the capital of Quebec province, is situated on the north bank of the St. Lawrence river at its junction with the St. Charles, about 400 mi. (644 km.) from the Atlantic ocean and 180 mi. (290 km.) by river northeast of Montreal. It consists of an upper and a lower town. The upper town is built on the northern extremity of an elevated tableland which forms the left bank of the St. Lawrence for a distance of 8 mi. (13 km.). The highest part of the headland is Cape Diamond, 333 ft. (101 m.) above sea level, and crowned by the Citadel; toward the St. Lawrence it presents a bold and precipitous front, while on the landward side and toward the St. Charles the declivity is more gradual. The lower town is built all around the tableland, at the foot of the cliffs and in the basin of the St. Charles river, and expands on the Beauport coast. Steep, winding streets and an inclined elevator connect the two towns.

The climate of Quebec is severe but bracing, the mean temperature in winter being 12° F (about -11° C) and in summer 68° F (20° C). The city returns four members to the provincial house of assembly and three to the house of commons.

History.—The first known white man to visit Quebec was Jacques Cartier, the French navigator who, in 1535, found on the site a large Indian village called Stadacona. In July 1608, the present city was founded and named by Samuel de Champlain. The origin of the name Quebec has been much disputed, but it is apparently the Algonkian word for a sudden narrowing, a strait, such as the case opposite Cape Diamond where the St. Lawrence narrows to 1,314 yd. (1,202 m.).

The most westward French settlement in America, Quebec was captured in 1629 by the English under Sir David Kirke. They held it until the treaty of St. Germain-en-Laye of 1632, when it was restored to the French. When the colony of New France was made a royal province in 1663 Quebec became the capital and the centre of French operations in North America for a century. In 1690, Sir William Phips, governor of Massachusetts, attempted to reconquer it with a fleet and army but was defeated by the French governor, the comte de Frontenac. In 1711 a great British expedition sent against Quebec under Sir Hovenden Walker was shipwrecked in the Gulf of St. Lawrence, and the French held possession until the French and Indian War. In 1759, a young British general, James Wolfe (q.v.), was given the command of an expedition against Quebec from the lower St. Lawrence, while Lord Jeffrey Amherst led a force from New England by Lake Champlain on Montreal. With 8,000 men convoyed by a powerful fleet, Wolfe tried unsuccessfully to disembark at Beauport and Montmorency below the city; seizing Point Lévis, he bombarded Quebec from there. Many weeks later he decided to land at the Foulon cove above Quebec, and move the main body of his troops to the top of the cliffs on the heights of Abraham. There he was able to fight and defeat the French army commanded by the marquis de Montcalm. Both Wolfe and Montcalm were killed. Quebec surrendered on Sept. 18, five days after the battle. New France

was ceded to Great Britain by the treaty ending the war in 1763.

In the winter of 1775–76 American forces under Richard Montgomery and Benedict Arnold attacked the city, but Montgomery was killed (Dec. 31, 1775) and Arnold was compelled to retreat in the following spring. Quebec was the capital of the province of Quebec (1763–91) as then existing; the capital of Lower Canada (1791–1841); the capital of the United Province of Canada, 1851–55 and again in 1859–67; and from 1867 the capital of the province of Quebec. During World War II Pres. Franklin D. Roosevelt and Prime Minister Winston Churchill held a conference at the Citadel in 1943, known as the Quebec conference, that prepared for the invasion of Europe by Allied forces.

Urban Characteristics.—The most notable feature of Quebec is the city within the walls, the only remaining enclosed city in North America. The present walls and the Citadel that crowns Cape Diamond cover an area of about 40 ac. (16 ha.); they were built in 1823–32. Since then several of the gates have been destroyed and others rebuilt; among the best-known are St. Jean and St. Louis gates. Between 1865 and 1871 three forts were built on the Lévis side of the river but these were neither manned nor armed.

In the city, with its narrow and irregular streets, the visitor will discover the old world character of Quebec. Several houses built during the French regime are still occupied. Among the famous buildings located in this part of Quebec are the Château Frontenac, a large hotel erected by the Canadian Pacific railway; the Anglican cathedral, built in 1804; the Roman Catholic basilica, founded in 1647, enlarged at various times, destroyed by fire in 1922 and rebuilt on the original site; the old Roman Catholic seminary, founded in 1663; Laval university; and the Ursuline convent. The Dufferin terrace is a magnificent 1,400-ft. (427-m.) long promenade overlooking the St. Lawrence, 200 ft. (61 m.) above the level of the river. From the terrace one can see the Laurentian hills, Île d'Orléans, the Lauzon-Lévis south shore communities, the ferry boats plying between the banks of the St. Lawrence, the traffic of ships on the river, and the lower town with the Louise basin and some of the port facilities such as the grain elevator. During the winter, the terrace is a favourite winter sport centre for skating and toboggan rides. The lower town (*basse-ville*) is a mixture of old buildings such as the Notre Dame des Victoires church (erected in 1688, but so named in memory of the defeats of Phips in 1690 and Walker in 1711), old houses and new warehouses and other commercial buildings. It is the financial and wholesale district of Quebec.

In the upper town, beyond the walls, are the historic Plains of Abraham, a national battlefield park and site of the museum of the province of Quebec; the parliament buildings of French Renaissance style, built in 1878–92; and the Bois de Coulouge residence, seat of the lieutenant governor of the province.

Churches and Institutions.—The numerous spires and towers of buildings are another distinctive feature of Quebec. The city is 90% Roman Catholic and 92% French Canadian; many religious orders and congregations have established their mother houses there. Laval university, named after the first bishop of Quebec, was founded in 1852 by royal charter from Queen Victoria and in 1876 received a charter from Pope Pius IX. It includes faculties of theology, philosophy, law, medicine, sciences, arts, letters, forestry and commerce, a library, a museum and a picture gallery. In 1952 the university began its move to a new campus in the suburb of Sainte-Foy. The principal benevolent institutions of Quebec are also administered by religious congregations. The Hôtel Dieu, one of the largest hospitals of the city, was founded in 1639 by the duchess of Aiguillon and has continuously served the public. Under the dual system of education in the province (French and English), there are two separate groups of primary and secondary schools and colleges. A number of government buildings are scattered over the city and in some of the suburbs.

Commerce, Industries and Transportation.—Quebec was long the chief port of Canada and one of the most important wooden shipbuilding and repair centres on the continent. With the deepening of the St. Lawrence channel upstream in the second half of the 19th century, Montreal became the great shipping port

of Canada and Quebec suffered a serious economic setback. Later, with the construction of railway lines in all directions from the old capital, the building of new harbour facilities, the abundant services of hydroelectric power and the availability of skilled labour, an important industrial development followed. The chief industries are shipyards and shipbuilding, pulp and paper, shoe and leather, textiles, clothing, mechanical industries, gunpowder, ropes and food and beverages. Quebec is the main trade and commercial centre of the eastern part of the province. The principal commodities handled in the port are grain, coal, petroleum products, asbestos, steel, cement, pulp and paper, newsprint and general cargo. The port, formerly icebound between Christmas and the end of March, is now open to winter navigation. Quebec harbour is the seat of the regional administrator of the federal department of transport for marine operations, who is responsible for the maintenance of the St. Lawrence waterway from the ocean to Quebec. From the Dufferin terrace one can see the Queen's wharf at the bottom, where arctic supply ships are loaded, buoys manufactured and repaired, maintenance barges and ships loaded or unloaded and icebreakers assigned to special duties in the winter.

To improve transportation of passengers and commodities between the municipalities on both shores of the St. Lawrence, the Quebec bridge, 7 mi. (11 km.) above the city, was completed in 1917, after ten years of work and two serious accidents to the structure (on both occasions one of the sections fell into the river). It is used by railway and vehicular traffic. Quebec is a major railroad centre, the terminal of the transcontinental line from Prince Rupert (British Columbia), the Lake St. John-Saguenay line and the North Shore line to Murray Bay (La Malbaie). These lines and the modern freight yard of Charny are operated by the Canadian National railway. Quebec is also the terminal of the Montreal-Quebec line of the Canadian Pacific railway and is linked with major Canadian and U.S. cities by bus and truck transport service. The Quebec airport is located at Ancienne-Lorette, 10 mi. (16 km.) W. of the city, and is served by Trans-Canada air lines and Quebecair, with several daily flights to Montreal, Chicoutimi, the iron ore district of Sept-Îles-Schefferville and other Canadian metropolitan districts.

The Quebec metropolitan area has a population (1961) of 357,568 (Quebec city proper, 171,979) and comprises 30 municipalities; several of these municipalities are located on the south shore, Lévis and Lauzon being the most important ones. Sainte-Foy and Sillery are two residential suburbs in the upper town. There is a Huron Indian reservation near Loretteville.

QUEBEC ACT, an act of Parliament assented to on June 22, 1774, that vested the government of Quebec in a governor and council and preserved the French Civil Code and the Roman Catholic religion. The act was an attempt to deal with major questions that had arisen during the attempt to make the French colony of Canada a province of the British Empire in North America. Among these were whether an assembly should be summoned, when nearly all the inhabitants of the Province of Quebec, being Roman Catholics, would, because of the Test Acts (q.v.), be unable to be representatives; whether the exercise of the Roman Catholic religion should be allowed to continue, and on what conditions; and whether French or English law was to be used in the courts of justice.

The act, declaring it inexpedient to call an assembly, put the power to legislate in the hands of the governor and his council. The exercise of the Roman Catholic religion was allowed, and the church was authorized to continue to collect the tithe. The Test Act was waived and an oath of allegiance substituted so as to allow Roman Catholics to hold office. French civil law continued, but the criminal law was to be English. Because of these provisions the act has been called a generous and statesmanlike attempt to deal with the peculiar conditions of the province.

At the last moment additions were made to the bill by which the boundaries given the province by the Proclamation of 1763 were extended. This was done because no satisfactory means had been found to regulate Indian affairs and to govern the French settlers on the Ohio and Mississippi rivers. It was decided, therefore, to put the territory between the Ohio and the Mississippi under the governor of Quebec, and the boundaries of Quebec were extended southward to the junction of the Ohio and the Mississippi and northward to the height of land between the Great Lakes and Hudson Bay.

This provision of the act, together with the recognition of the Roman Catholic religion, was seen to threaten the unity and security of British America by in effect reviving the old French Empire destroyed in 1763. The American colonists viewed the act as a measure of coercion. The act was thus a major cause of the American Revolution, and provoked an invasion of Quebec by the armies of the revolting colonies in the winter of 1775-76. (See AMERICAN REVOLUTION.) Its provisions, on the other hand, did little at the time to win French support of British rule in Quebec and, except for the clergy and seigneurs, most of the French remained neutral. The act eventually became important to French Canadians as the basis of their religious and legal rights.

(W. L. Mo.)

QUEDLINBURG, a town of East Germany in the *Bezirk* (district) of Halle, German Democratic Republic. It is situated on the Bode, 48 mi. (77 km.) SW of Magdeburg by road in the fertile northern foothills of the lower Harz Mountains. Pop. (1962 est.) 31,128. Quedlinburg has town walls and towers and many half-timbered buildings, the oldest dating from the 10th century. The town is dominated by the castle, now a museum, and the abbey church of St. Servatius (now Protestant), a Romanesque basilica. Paints, precision instruments, engineering products, wagons, chemical and pharmaceutical goods, and jewelry are produced and it is an important seed-growing centre, the Institute for Plant Research being situated there. The town is said to have been founded by a certain Qutilo in the 5th century. Henry I built the castle and is buried in the abbey church. In the 10th and 11th centuries Quedlinburg was an important intellectual centre and was often the residence of the Saxon German emperors. Until 1477 it was part of the Hanseatic League, and then came under the protection of the elector of Saxony. In 1698 it passed to the elector of Brandenburg. The poet Friedrich Gottlieb Klopstock (1724-1803) was born in Quedlinburg.

QUEEN ANNE'S BOUNTY: see CHURCH COMMISSIONERS.

QUEENBOROUGH, a municipal borough in the Faversham parliamentary division of Kent, England, in the Isle of Sheppey near the junction of the Medway and Swale rivers, 3 mi. (5 km.) S of Sheerness. Pop. (1961) 3,044. In 1339 the marshes were drained and the town's foundations laid. In 1361 Edward III replaced a nearby Saxon fortress by the castle, designed by his chancellor William of Wykeham. From 1582 until demolished by Cromwell this was the official residence of the lord warden of the Cinque Ports. Edward III named the town Regina Burgia when he stayed there with Philippa, his queen, in 1366, granted it a charter with markets and fairs, and built the parish church. The guildhall contains valuable old regalia. Queenborough was a wool staple town in Tudor times and prospered still more when, in 1579, Matthias Falconer started manufacturing chemicals. This industry still goes on; others include glassmaking, ironfounding, the production of sanitary pottery, and the importation and distribution of coal.

QUEEN CHARLOTTE ISLANDS, a compact group lying off the northern part of the coast of British Columbia, form part of that province of Canada. Pop. (1961) 3,014 (including about 950 persons living on Indian reserves). Land area 3,705 sq.mi. (9,596 sq.km.). The islands were named after his ship by Capt. George Dixon who, in 1787, sailed through Hecate Strait, which separates them from the mainland. The islands contain resources of minerals (coal, gold, silver, and copper) and softwood timber. The surrounding waters support prolific fisheries (chiefly salmon,

halibut, herring, crabs, and clams), but comparatively little settlement has occurred. The largest community, Queen Charlotte, had less than 500 inhabitants in 1960. Logging and fishing are the main occupations, most of the output going to processing plants on the mainland. There are scheduled air and marine transport connections with Prince Rupert but bad weather often disrupts the service, especially in winter. The native Haida Indians possessed one of the highest cultures and art forms found among aboriginal peoples of northwestern America. (A. L. Fy.)

QUEEN ELIZABETH ISLANDS, the name given in 1953 to the groups of islands of the Canadian Arctic archipelago north of latitude 74° 30' N in honour of Queen Elizabeth II. The islands are the most northerly land area of North America and are almost completely uninhabited. Total area 134,920 sq.mi. (349,443 sq.km.). Pop. (1961) 310. The largest is Ellesmere (q.v.; 82,119 sq.mi. [212,688 sq.km.]); ranking next in size are Devon (20,861 sq.mi. [54,030 sq.km.]); Melville (16,141 sq.mi. [41,805 sq.km.]); and Axel Heiberg (15,779 sq.mi. [40,919 sq.km.]). Administratively, the islands are a part of Franklin District of the Northwest Territories (q.v.). For their geology, exploration, and the like, see ARCTIC, THE.

QUEENS, the largest of the five boroughs of the city of New York, U.S. Located on western Long Island, it extends across the island from the junction of the East River and Long Island Sound to the Atlantic Ocean; Queens County is coterminous with the borough. In the early Colonial period the area was part of New Netherland and the first settlement was made by the Dutch in 1636 near Flushing Bay. Gradually towns were organized, including Newtown in 1642, Far Rockaway in 1644, Flushing in 1645, and Jamaica in 1656. These settlements along with the rest of New Netherland came under English control in 1664 when Peter Stuyvesant surrendered to an English force acting for the duke of York. In 1683 the English established Queens County as one of the 12 counties of the province of New York. It was named for Catherine of Braganza, queen consort of Charles II.

During the American Revolution the residents of Queens County were divided in their allegiance; when the English captured Long Island in 1776 many of the patriots fled, and at the conclusion of the struggle a group of the Tories migrated to Newfoundland.

Throughout the 19th century Queens continued to be primarily a rural community with a few small trading centres. Some of the shore communities began to attract large numbers of summer vacationists and such popular resorts as the Rockaways became well known. In 1898 Queens borough was formed as a part of greater New York and at the same time assumed its present size (126.6 sq.mi.) when the three eastern towns of Hempstead, North Hempstead, and Oyster Bay opposed joining New York City and were chartered as Nassau County. Pop. (1960) 1,809,578.

Queens experienced rapid development after the opening of the Queensboro Bridge in 1909 and the Long Island Railroad tunnel the next year. This development continued and Queens became the fastest growing borough of the city, still retaining for the most part its residential character. See also LONG ISLAND; NEW YORK (CITY).

QUEEN'S (KING'S) BENCH, COURT OF, in England, was descended from the court held *coram rege* ("before the monarch") when it was part of that undifferentiated *curia regis* (see HOUSEHOLD, ROYAL) which was still performing legislative and executive as well as judicial functions. It was a court to hear cases which concerned the sovereign, or cases affecting great persons privileged to be tried only before him. If he was absent abroad, such cases were heard *coram consilio nostro* ("before our council"). It was also a court to correct the errors and defaults of all other courts, and after the close of the civil wars of Henry III's reign was mainly occupied with the trial of criminal or quasi-criminal cases. In 1268 it obtained a chief justice of its own, but only very gradually did it become a separate court of common law. Thus it was not until a century after the Court of Common Pleas (q.v.) had become a distinct court of common law that the Court of King's Bench attained a similar position.

It exercised a supreme and general jurisdiction, which comprised (1) criminal jurisdiction; (2) civil jurisdiction; and (3)

jurisdiction over the errors of inferior courts including those of the Court of Common Pleas, until by the act of 1830 the Court of Exchequer Chamber became a court of appeal intermediate between the three common law courts and Parliament. It also heard appeals from the Court of King's Bench in Ireland until 1783, and exercised jurisdiction over officials and others by means of the prerogative writs; e.g., habeas corpus, certiorari, prohibition, mandamus, quo warranto, and ne exeat regno.

By the Judicature Act, 1873, the court was merged in the Queen's Bench Division of the High Court of Justice. It consists of a chief justice—now lord chief justice of England—and not less than 17 out of the total number of subordinate judges authorized by the High Court and County Court Judges Act, 1950, as amended by the Restrictive Trade Practices Act, 1956; there are 24 judges assigned to this division. Appeals from inferior courts come before a divisional court, composed of two or three judges of the division. See also COURT; PRACTICE AND PROCEDURE.

(H. H. L. B.; W. T. Ws.)

QUEENSBERRY, EARLS, MARQUESSES, AND DUKES OF. The Queensberry title, one of the many associated with the Scottish house of Douglas (q.v.), originated when Sir WILLIAM DOUGLAS (d. 1640) was created earl of Queensberry in 1633. He was a direct descendant of Sir William Douglas (d. c. 1421), illegitimate son of James (d. 1388), 2nd earl of Douglas, who received from his father a grant of the lands of Drumlanrig in Dumfriesshire.

Sir William's grandson, WILLIAM (1637–1695), was created marquess of Queensberry in 1682, and in 1684, as a reward for his services in helping suppress the Scottish covenanters, duke of Queensberry. From 1682 to 1686 as lord high treasurer of Scotland he wielded great power. He supported the revolution of 1688, taking the oath of allegiance to William and Mary in April 1690. His son JAMES (1672–1711), 2nd duke, also supported the revolution. He held many offices in Scotland and was created (1701) a Knight of the Garter for his services as commissioner to the Scottish Parliament. Deprived of many of his offices in 1704 as a result of his association with the Jacobite intriguer Simon Fraser, Baron Lovat (q.v.), he was restored in 1705, and in 1706 was commissioner for effecting the union between Scotland and England. In 1708 he was created duke of Dover and marquess of Beverley, both in the peerage of Great Britain.

The 2nd duke's eldest son died in infancy and his second son JAMES (1697–1715) was an idiot. In 1706 the 2nd duke resigned the dukedom of Queensberry and certain other of his titles and obtained a novodamus (regrant) by which he was able to arrange that they should pass on his death to his third son CHARLES (1698–1778). The titles of marquess and earl of Queensberry, not being mentioned in the novodamus, are presumed to have belonged *de jure* to James, between 1711 and 1715, although he was never so styled. His brother Charles was, therefore, after 1711, 3rd duke, and after 1715, since James died unmarried, 4th marquess and 6th earl of Queensberry. The 3rd duke was keeper of the great seal of Scotland from 1761 to 1763, and lord justice general in Scotland from 1763 until his death.

Charles's two sons predeceased him, and on his death the dukedom of Dover (of which he had had special remainder by the creation of 1708) and the marquessate of Beverley became extinct. His Scottish titles descended to a cousin, WILLIAM DOUGLAS (1725–1810), 3rd earl of March, grandson of William, 1st Douglas earl of March, younger brother of James, 2nd duke of Queensberry. He was lord of the bedchamber to George III from 1760 to 1789, when he was dismissed for having opposed the government on the regency question (1788). A notable personality in the racing world, the 4th duke was often known as "Old Q" or "the star of Piccadilly." He died unmarried and the earldom of March passed to a distant cousin, Francis Charteris (afterward earl of Wemyss). Because of the 1706 novodamus, the dukedom of Queensberry again became separated from the marquessate and the earldom. The former, with the Drumlanrig lands, went to the 2nd duke's second cousin once removed, HENRY SCOTT (1746–1812), 3rd duke of Buccleuch, and is presently held by his direct descendant SIR WALTER JOHN MONTAGU-DOUGLAS-SCOTT.

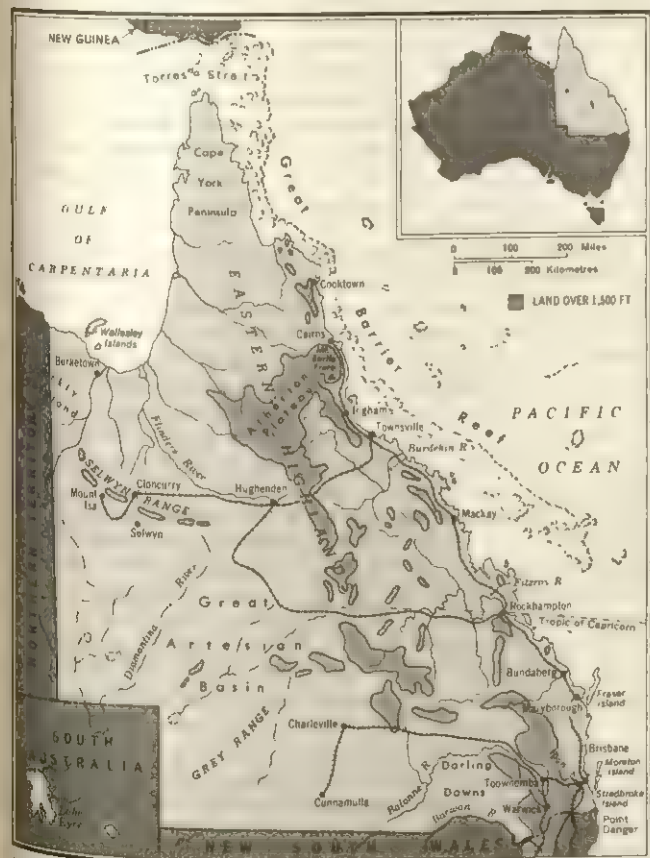

(1894–), 8th duke of Buccleuch and 10th duke of Queensberry. The marquessate and earldom passed to SIR CHARLES DOUGLAS (1777–1837), 5th baronet, a descendant of William, 1st earl of Queensberry.

Charles died without male issue and the dignities passed to his brother JOHN (1779–1856) and to John's heirs. JOHN SHOLTO DOUGLAS (1844–1900), the 9th marquess, was a boxing enthusiast and the Queensberry rules, which govern the sport in Britain, were drawn up under his auspices. DAVID HARRINGTON ANGUS DOUGLAS (1929–) is 12th marquess.

QUEENSLAND, a state of Australia in the northeast of the continent occupying 667,000 sq.mi. (1,727,532 sq.km.), or about one-fifth of the total area. A coastline of 3,236 mi. (5,208 km.)—after that of Western Australia the longest of any individual state—bounds it on the north from the Gulf of Carpentaria and on the northeast and east from the Coral Sea and the Pacific Ocean respectively, the 480-mi. (772-km.)-long Cape York Peninsula forming the only major irregularity in the coastal plan. In the west the boundary runs successively with that of Northern Territory along longitude 138° E and with that of South Australia along latitude 26° S and longitude 141° E to the northwest corner of New South Wales. In the south the boundary marches with that of New South Wales along latitude 29° S, the Barwon-Macintyre-Dumaresq rivers and the crest lines of the McPherson Range to Point Danger. The waters and islands of Torres Strait nearly to New Guinea, as well as the Great Barrier Reef, are included within the political boundaries. Maximum length (north-south) is 1,238 mi. (1,992 km.) and maximum breadth (east-west at latitude 26° S) is 945 mi. (1,521 km.). The capital is Brisbane (*q.v.*).

PHYSICAL GEOGRAPHY

Physical Features.—Queensland is characteristically an area of subdued relief. Great plains extend over wide areas of the state, and, although they merge into higher country of sharper relief both to the east and the northwest, there are relatively small tracts of country that are mountainous.

PHYSICAL FEATURES, MAJOR CITIES, AND RAILROADS OF QUEENSLAND, AUSTRALIA

DOUGLASS BAGLIN

DIVIDING RANGE IN THE EASTERN HIGHLANDS NEAR HUGHENDEN, QUEENSLAND

The Eastern Range, Plateau, and Lowland Region.—This area occupies the eastern quarter of the state between the Main Divide (as the western continuation of the Eastern Highlands is called in Queensland) and the Pacific coast. In the north, however, its western limits extend beyond the Main Divide. It is underlain mainly by Paleozoic rocks, folded into complex structures and invaded by widespread igneous intrusions between Devonian and Permian times, with a superposition of Mesozoic sediments in some central and southern basins and with Tertiary basalt-flow residuals capping many of the higher areas. The two main components in the surface configuration pattern are the coastal ranges—a discontinuous and much-denuded series of low ranges and plateaus, often with cores of granitic rocks and flanks of metamorphics—and the present Main Divide which follows generally the upwarped eastern rim of the Mesozoic rocks of the Great Artesian Basin. Between these two structural swells is a series of extensive, shallow, interior basins and narrow, near-coastal lowland corridors separated by ranges and plateaus.

The Main Divide follows a course that is convex to the southwest, so that the region has its greatest width (about 300 mi. [488 km.]) near the Tropic of Capricorn. In this central area, too, elevations are lowest, the great interior catchment basins of the Fitzroy and Burdekin river systems (occupying about 54,500 and 53,500 sq.mi. [141,000 and 138,500 sq.km.] respectively) with their markedly convergent tributary patterns being mostly undulating lowland westward of the coastal ranges. The dominant structural feature of this central area is the huge Bowen syncline, a downwarp including the most extensive bituminous coal measures in Queensland.

Northward and southward from the tropic, the coastal and Main Divide ranges become more conspicuous and continuous and converge to form the most striking ranges and highest plateaus in the state. In the far north the Atherton Plateau of about 12,000 sq.mi. (31,000 sq.km.) everywhere exceeds 2,000 ft. (600 m.) and rises irregularly southward to more than 3,000 ft. (900 m.). Pliocene basalt, weathering into rich red soils, covers much of its area, and the Bellenden Ker Range with Queensland's highest peak, Mt. Bartle Frere (5,287 ft. [1,612 m.]), bounds it on the east. In the far south, the rugged McPherson Range (Mt. Barney, 4,449 ft. [1,356 m.]) lies astride the state border inland from Tugun beach for 60 mi. (100 km.), merging thence into the highest part of the Queensland Main Divide (Mt. Superbus, 4,525 ft. [1,379 m.]) which there presents a steep face to the east but a slighter and

more gentle descent westward toward the Darling Downs. The rivers in these mountainous areas have a more uniform flow than those of east-central Queensland. The latter are classed as perennial, but considerable stretches of their courses dry out in winter.

The Pacific coastline cuts transversely across the structural grain and is characterized by an alternation of rocky, north-facing promontories, sheltering picturesque inlets and gently curving sandy beaches, often backed by sand dunes and salt marsh. The rivers generally flow to the sea across deltaic plains, those of the Burdekin and Fitzroy being of considerable size. The long, narrow islands close off the southern coast (Fraser, Bribie, Moreton and Stradbroke) are composed of sand dunes which are among the highest in the world. The string of reefs and cays, collectively known as the Great Barrier Reef, that stretches for more than 1,100 mi. (1,770 km.) from Torres Strait to latitude 24° S, lies along the seaward margin of the continental shelf. (See BARRIER REEF.) The coast along the Gulf of Carpentaria is low lying and mangrove lined.

The Western Plains.—These plains occupy more than half the area of Queensland and form a great tract of lowland extending continuously from the Gulf coast to the southern border but constricted to a width of 280 mi. (450 km.) in the low Kynuna watershed (latitude 21° S), an upwarped structural and surface swell (600–1,200 ft. [180–370 m.] generally rising eastward) with occasional low ridges. Northward and southward from this swell and westward from the hill country flanking the western side of the Main Divide there is a very gentle over-all slope northwestward toward the Gulf of Carpentaria and southwestward toward the Lake Eyre region, corresponding with two great shallow sags in the thick Cretaceous sandstones and shales that underlie the plains. These slopes are closely followed by the watercourses which form three systems converging respectively toward the Darling in the south, the Lake Eyre flats of South Australia in the southwest, and the Gulf of Carpentaria in the northwest. Some of these watercourses are of considerable length but most flow only for short periods each year following the summer rains. In floodtime the Channel country of the far southwest is widely inundated, but with the loss of water by evaporation and seepage the waters rarely reach Lake Eyre.

West of the Channel country and astride the southwestern boundary of the state is a tract of fixed and partly vegetated sand dunes aligned generally along north-northwest axes.

The extent of the western plains coincides fairly closely with that of the Queensland part of the Great Artesian Basin with its underlying strata of water-bearing rocks.

The Northwest Uplands.—In the far northwest of Queensland is an outlier of the Precambrian rocks of the Australian shield trending north-northwest for 300 mi. (480 km.) from near Selwyn and Dajarra to the state border west of Burketown. Especially in the south, the rocks are closely folded, intimately penetrated by igneous intrusions, and locally mineralized. Dissected hill country with steep-sided rocky valleys characterizes this area. The Georgina Plains west of Mount Isa are floored by Cambrian limestones and rise gently northward to the Barkly tableland.

Climate.—Queensland is divided into almost equal parts by the Tropic of Capricorn and includes comparatively little high country, so that hot summers and mild winters are characteristic of the state. The rainfall shows a well-marked summer maximum and varies widely. The heaviest rains occur in the northeast coastlands between Cooktown and Ingham and on the mountain slopes immediately to the west (Tully, 178.06 in. [4522.7 mm.]). The heaviest and most prolonged falls are from December to March.

(R. H. G.)

Vegetation.—Rain forest with strong Papuan floristic affinities occurs in the higher rainfall districts, reaching its best development along the eastern coast in scattered areas with an annual rainfall of about 60 in. (1,520 mm.) or more. Inland, with a decreasing annual rainfall and a marked dry season, it passes gradually into monsoon forest and farther west, in the areas of less than 30 in. (760 mm.) of rainfall, it disappears as a vegetation unit. The predominant vegetation type in a belt about 250 mi.

(400 km.) wide along the eastern coast is eucalyptus forest, interspersed with extensive grasslands. The eucalyptus forests are the source of valuable hardwoods and the rain forests provide many important cabinet timbers. With increasing aridity the eucalyptus forests thin out, and the great pastoral areas stretch to the edge of the desert in the extreme west of the state. Extensive mangrove forests occur in the estuaries and on tidal mud flats, especially in the tropical north.

Animal Life.—Terrestrial mammals native to Queensland include the 2 monotremes (echidna and platypus), more than 50 species of marsupials, and more than 50 of placental mammals. The echidna is common, and the platypus is more abundant in the southern part of the state than in the far north. Marsupials range in size from the great gray kangaroo to a two-inch broad-footed pouched "mouse." Numbers of some species such as the koala have been greatly reduced as the result of settlement. Some, however, have adapted themselves to urban conditions, notably the brush-tailed opossum and the short-nosed bandicoot. Two species of tree-climbing kangaroo and two of the cuscuses in the north are examples of links with the marsupial fauna of New Guinea. Destructive carnivorous marsupials are few, the native "cat" (*Dasyurus*) being the largest. Among placental mammals are the dingo, bats (including some destructive fruit-eating species, the flying foxes), and rodents. Of the snakes the largest authentic specimen is of *Python amethystinus*, 12½ ft. long, from north Queensland. Lizards are common and among the turtles is the edible green turtle. Notable among the birds are the emu, cassowary, and several kinds of birds of paradise and bowerbirds. Marine fish species are numerous and of the freshwater species the lungfish (*Neoceratodus forsteri*) is of special interest. The corals and other marine life of the Great Barrier Reef are of extraordinary richness, and there is a marine biological research station at Heron Island in the Capricorn group.

National Parks.—About 100,100 ac. (40,500 ha.) of national parks have been permanently reserved under the protection and administration of the Forestry Department. They vary from a few acres to whole mountain ranges such as in the Carnarvon National Park of 66,480 ac. (26,900 ha.). Essentially they are natural reserves maintained in their original state except for access paths and, where necessary, accommodation areas for visitors. The parks, which are designed to preserve a full range of habitats of Queensland plants and animals against the encroachment of settlement, are of diverse types, ranging from coral islands to mainland forests.

(D. A. Ht.)

HISTORY

By 1606 both the Dutch and the Spanish explorer Luis de Torres had found Cape York Peninsula, but it was 1770 before Capt. James Cook discovered the east coast of Australia and the Torres Strait itself, and removed the great southern continent from centuries of fireside speculation. Cook noted signs that a great river might empty into Moreton Bay. Matthew Flinders in 1799 denied it, but in 1823 John Oxley, with the aid of castaways, discovered the Brisbane River and chose its neighbourhood as the new penal settlement that the government at Sydney wished to establish in the then remote north.

Allan Cunningham's discovery of the Darling Downs (1827) pointed the way to more flourishing settlement, which had already begun overland from the south when in 1839 the abolition of the penal colony facilitated healthy development. The early squatters were followed in 1842 by the first free settlers, and sales of land took place. The main hindrances then became the remoteness of Moreton Bay district, the lack of understanding of the region in Sydney and the consequent small number of settlers—no more than 2,000 in the mid-1840s. It was 1840 before Patrick Leslie ventured on the downs at Warwick with sheep, and the first arable farmers, apart from the Moravian missionaries at Nundah in the penal days, were brought by J. D. Lang in the "Fortitude" in 1849. It was therefore mid-century before emigrant ships from Britain sailed directly to Brisbane. Nevertheless, political separation from New South Wales was achieved in 1859, when the population numbered only 23,520 and before any industry had estab-

lished itself, though gold had been discovered in 1858.

Coal was found at Ipswich as early as 1827 and the first mine opened in 1846, but it was the gold rush that really inaugurated Queensland's mining industry. From 1858 to 1873 the east and north of the state were invaded and opened up by diggers at Canoona, Peak Downs, Gympie, Ravenswood, Charters Towers, and Palmer River. Within a few months isolated spots in the bush became townships of 10,000 people. There some of the beginnings of the "White Australia" policy may be seen in the discrimination by act of Parliament against Chinese and other Asian speculators (1877). By 1867 the population of the state had grown to 100,000. Even where the gold failed, as at Canoona, a town such as Rockhampton could rise from the ruins. In 1882 came the discovery of a mountain of gold and copper, Mt. Morgan; in the 1920s the finding of the silver-lead-zinc deposits at Mt. Isa; and after World War II the discovery of uranium at Mary Kathleen and bauxite in great quantity in Cape York Peninsula.

In the 1860s westward migration was very rapid wherever there was water, and the movement was encouraged in 1869 by an act of Parliament which granted 21-year leases to those who had 25 sheep or 5 cattle to the square mile. Many of the early pastoralists failed. Wool had to be transported in drays by long trains of bullocks and markets were far away and uncertain. But by 1873 Victorian prosperity (in gold) began to be invested in Queensland. Sheep studs were improved, and fences replaced the shepherd. The first railways, from Ipswich to Dalby and Warwick, were operating by 1870. In the 1880s attempts were made, not always successfully, to end the bitter struggle between grazier (livestock rancher) and squatter by a succession of acts of Parliament. Artesian boring was introduced in 1881 and was energetically developed after the bad years of drought and depression between 1890 and 1902, which wiped out flocks and herds. In addition, after 1894 cattle suffered the onslaught of the cattle tick from northern Queensland, and an industry which had been stimulated by the advent of refrigeration and which had made its mark on Australian life in the tradition of droving over huge distances saw its 7,000,000 cattle halved by 1902. After World War II, however, improved insecticides and communications helped the cattle farmer.

There was similar strife between the early arable farmer and the grazier who had come before him. Hewing out his farm by clearing the bush, attempting crops where none had ever been cultivated, the farmer won the contemptuous name of "cockatoo farmer." But, supporting himself, he advanced from maize (corn) and pumpkins to lucerne and sorghum; his livestock increased; and the plow, reaper, and farmhouse replaced the hoe, scythe and sickle, and bark hut. By 1900 the government had recovered much pastoral land for the arable farmer, and by the mid-20th century land which had originally belonged to graziers had become renowned for wheat, sugarcane, and bacon.

Dairying did not flourish till the 20th century, when there were sufficiently populous towns to give it encouragement. Until 1888 Queensland imported much of its butter from the south, but by 1895 it had become self-sufficient in dairy products.

Between 1860 and 1904 Queensland was closely involved in the long dispute over the employment of South Sea islanders (Kanakas) as cheap labour. The recruiting of Kanakas (often against their will) began with the introduction of cotton cultivation when the American Civil War threw the cotton market open, and, after cotton failed at the end of the war, continued with the growth of the sugarcane industry. The replacement of the hoe by the plow and the greater productiveness of the white man lessened the usefulness of the Kanakas; by an act of 1904 the new federal government ended the importing of coloured labour and agreed to support sugar financially, when necessary, in the interests of the "White Australia" policy. The early system of large estates with their own mills was superseded by one of small growers with central mills, encouraged by the government and often working as cooperatives.

The Kanaka problem influenced the separatist movement in northern Queensland (where both sugarcane and the goldfields were), but whereas the planters wanted separation the miners did

not, fearing that the planters would impose a policy of continued importation of coloured labour. From the same fear, and because of Queensland's lack of maturity in government, Britain disallowed the colony's annexation of eastern New Guinea in 1883, though increasing trade and Germany's expansion in the Pacific forced Britain to annex southeastern New Guinea in 1884.

Toward the end of the 19th century the increase in population, the advance of social legislation in Europe, the socialist idealism of William Lane, and the depression of the 1890s encouraged the growth of trade unionism and led to the emergence of a Labour Party with well-defined policies. The most notable event in Queensland at this period was the shearers' strike in 1891. It was broken, but subsequent legislation providing for shorter working hours, improved conditions of work, and the encouragement of the smaller settler showed clearly the trend of the times. In 1899 Queensland had Australia's first Labour government, though a minority one, but Labour's position rapidly became so strong that after World War I it was almost continuously in office. In 1922 it abolished the upper house of Parliament. Among its most successful measures was the handling of agriculture through local producer cooperative boards.

(J. M. Cr.)

POPULATION, ADMINISTRATION, AND SOCIAL CONDITIONS

Population.—At the 1961 census the population of Queensland was 1,518,828 (excluding full-blooded aborigines, estimated at 11,445 in 1961, and 8,009 Torres Strait islanders). This represented 14.36% of the total for Australia and an average density for the state of 2.3 persons per square mile. The vital statistics for Queensland compare favourably with those for other Australian states. The crude birth rate during the decade 1951–60 was 24.0 per 1,000 of population per year, and the crude death rate over the same period was 8.54 per 1,000 per year. In 1961 metropolitan Brisbane had a population of 621,550. The population (1961) of provincial cities, the largest of which are coastal or near-coastal in location, was: Townsville (51,143); Toowoomba (50,134); Ipswich (48,679); Rockhampton (44,128); Gold Coast (33,716); Cairns (25,204); Bundaberg (22,799); Maryborough (19,126); Mackay (16,809). The greater part of the rural population is concentrated in areas near these cities.

Out of a total labour force of nearly 600,000, nearly one-fifth was employed in manufacturing industries and slightly smaller proportions in primary production and in commerce respectively.

Administration.—The government consists of the governor, the executive council (*i.e.*, the governor and the ministers in office), and a legislative assembly of 78 members elected by adult suffrage for a period of three years. There are three electoral zones, which are subdivided into electoral districts as follows: 28 metropolitan districts of about 12,000 electors, electing one member each; 8 provincial cities of between 10,000 and 15,000 electors, of which 4 elect one member and 4 elect two members; and 38 country zones of about 9,000 electors, electing one member each. Voting at elections is compulsory, as is electoral enrollment. The electorate consists of British subjects by birth or naturalization who have lived in Australia for six months and in the electoral district for three.

Local authorities are classed as either city, town, or shire councils, and in the early 1960s there were 14 cities and 2 towns of more than 7,000 persons, 3 other towns, and 112 shires. Councils are elected by adult suffrage and administer such services as public health and sanitation, roads, water, parks and amenities, and sometimes electricity and transport.

Health and Welfare.—In the early 1960s there were more than 130 public hospitals and sanatoriums supplying free consultation and treatment, nearly 120 public maternity hospitals, and just under 250 maternal and child welfare centres, dental clinics, and branches for free dental treatment. People living in remote parts of the state receive medical attention from the flying doctor service (*q.v.*). The state Department of Health also administers a school health service and a program of mental hygiene and industrial hygiene. In the early 1960s there were four mental hos-

pitals and a hospital for epileptic patients. The department has a guidance clinic for the treatment and prevention of maladjustment. Voluntary services include a hospital benefit scheme and medical benefit schemes. Maternity, child endowment, and widows' pensions, which are financed by the federal government, add to the social services available.

Education.—State education acts (1875–1964) established free and compulsory primary education up to the age of 15. In the mid-1960s there were about 1,300 state primary schools (just over half having average attendances of 40 pupils or less) with an enrollment of more than 215,000 pupils. In addition, nearly 2,000 pupils attended special schools for handicapped children. About 6,000 primary pupils in outlying parts of the state were receiving education by correspondence. Teachers in state schools numbered about 6,500 (primary) and about 2,200 (secondary). In the mid-1960s the secondary school course was increased from four to five years' duration. It accommodated about 66,000 children in nearly 90 state high schools and about 70 secondary departments attached to primary schools. There was also a system of private, denominational secondary schools. Technical colleges provide apprentice training throughout the state. There are two teachers' training colleges, and a training course for secondary-school teachers is provided by the University of Queensland. This university, established in 1909 and now at St. Lucia, has faculties in arts, science, engineering, commerce and economics, agriculture, law, dentistry, veterinary science, medicine, education, and architecture. In the mid-1960s its full-time teaching staff numbered about 800 and its students about 13,500. (F. J. SL.)

THE ECONOMY

Agriculture.—*Pastoral Industries.*—Livestock raising has played a fundamental part in the economic development of Queensland, and the net annual value of pastoral production in the early 1960s was about A£110,000,000 (including dairy products), considerably greater than that of agriculture (A£75,000,000), but less than that of manufacturing industries (A£175,000,000). The relative importance of pastoral as compared with agricultural production is largely a reflection of the low and unreliable rainfall over a large part of the state and the concentration of rainfall mainly within four summer months.

Although sheep and cattle are raised together on many properties, a belt of central Queensland extending from the southern border northward for 600 mi. (970 km.) through Charleville and Longreach to the Hughenden-Cloncurry downlands is used mainly for the raising of sheep and carries nearly all the sheep grazed in Queensland. This corresponds with the plains country, receiving between about 10 and 20 in. of rainfall and lying south of latitude 20° S. Almost all the animals are Australian merinos bred for their fine wool. Numbers fluctuate from year to year in relation

to variations in rainfall and pasture growth. Stock losses because of drought can be severe. In the early 1960s flocks totaled about 22,500,000 (about 14% of Australian sheep). The annual wool clip was about 233,000,000 lb. (greasy), valued at about A£53,000,000 (about 14% of Australian production).

Queensland is the leading Australian beef-producing state, carrying nearly 6,000,000 cattle (about half the national total) and producing about a third of Australia's output of beef and veal. The raising of cattle for beef takes place under a wide variety of conditions and over a much greater total area of Queensland than that of sheep. Cattle ranches are generally larger than those carrying sheep, about two-fifths of the stock being on holdings of 100,000 ac. (40,500 ha.) or more. Properties of 1,500 sq.mi. (3,900 sq.km.) are not unusual in the remote north and west. Zebu crossbreeds, more tolerant of dry feed, water shortages, and the cattle tick, have been introduced on a number of ranches. Slaughtering and freezing works at the ports of Brisbane, Gladstone, Rockhampton, Bowen, Townsville, and Cairns handle the bulk of the exported beef, the balance passing through Sydney, Melbourne, and Adelaide.

Dairy Production.—Dairying is a major industry in three high-rainfall areas—the southeast coastlands as far north as Rockhampton, the Darling Downs, and the Atherton Plateau. In the early 1960s the annual production of milk was about 225,000,000 gal., butter about 75,000,000 lb. (17.6% of Australian production), and cheese about 18,000,000 lb. (16%). Pig raising is closely associated with dairy farming in the south. In the early 1960s there were about 440,000 pigs (28%).

Crops.—The cultivation of crops is of major importance in the high-rainfall areas of the tropical east coast (sugar and fruit) and the Atherton Plateau (maize [corn] and peanuts), on the rich, moisture-holding soils of the Darling Downs and south and central Burnett areas (wheat, lucerne, sorghum, maize, cotton, and peanuts), and on the alluvial, volcanic, and red-earth residual soils of the southeast coastal region (maize, lucerne, fruit, and vegetables). The total area under crops in the early 1960s was about 3,000,000 ac. (1,200,000 ha.).

Sugarcane is the leading crop in terms of value of production. In the early 1960s about 8,800,000 tons (valued at about A£48,000,000) were cut annually, yielding about 1,300,000 tons of raw sugar (95% of Australian production). Refineries at Brisbane and Bundaberg meet the needs of Queensland consumers, the remaining sugar being exported—both to other states and overseas—mainly in its less perishable raw state.

In respect of acreage under cultivation, wheat is Queensland's leading crop (about 700,000 ac. in the early 1960s) though the value of the crop (about A£8,500,000) was much less than that of sugarcane. Production of wheat has increased markedly. In some measure this has been achieved by the more widespread use of drought-resistant varieties giving higher yields, but it has also been accompanied by a significant increase in area of cultivation. Production is concentrated mainly on the black soils of the Darling Downs (Warwick-Toowoomba-Dalby) and the chocolate soils of the South Burnett (Kingaroy) region. Cultivation and harvesting are highly mechanized.

Maize is grown on many of the mixed farms of southeastern Queensland to provide supplementary feed for stock, and it is also the main crop of the Atherton Plateau. Total annual production in the early 1960s was more than 4,600,000 bu. (valued at A£3,000,000). Grain sorghums are becoming increasingly important as feed for livestock and during the same period total annual production was nearly 7,000,000 bu. (valued at A£3,500,000). Peanuts are an important crop in the South Burnett region and on the Atherton Plateau. Production of other oil crops such as linseed and sunflowers is steadily increasing, but cotton growing declined after 1944 as a result of unfavourable seasons (dry farming methods are used), labour shortages, and comparatively low profit margins. Tobacco growing is now firmly established in the Border Rivers, Mareeba tableland, and Burdekin delta districts.

A variety of tropical and subtropical fruits and vegetables is grown on small holdings and mixed farms in coastal and near-coastal areas, the bulk of the production being within 100 mi. of

BY COURTESY OF AGRICULTURE AND STOCK, BRISBANE

HERDING CATTLE IN QUEENSLAND

Brisbane. Pineapples superseded bananas after 1940 as the chief fruit crop, the gross annual value of the pineapple crop in the early 1960s being about A£2,500,000. A substantial proportion of this crop is canned for sale in southern and overseas markets. Papaws and mangoes are grown in coastal areas; citrus fruits are concentrated mainly in the Gayndah, Maryborough, and Nambour areas of the southeast. The elevated "granite belt" around Stanthorpe, near the New South Wales border, is the only part of the state where apples, peaches, and plums are grown commercially, and this is also the chief grape-producing area.

Forestry.—Queensland forests are of three main types: the tropical rain forest (known locally as scrub or jungle) of the northeastern coastlands and ranges; the rain forests of the southeast; and the open forest covering most of the remainder of the eastern half of the state. Considerable areas of the tropical rain forest have been cleared for farming, but valuable reserves of silky oak, red cedar, Queensland maple, and Queensland walnut remain. The southeastern forests provide a higher proportion of native pinewood, especially hoop and bunya pine, and the state government is steadily increasing the area of afforested country by the planting of Caribbean and Mexican pine and the native hoop pine. The open forest of eucalypt hardwoods constitutes by far the greatest proportion of timber country in spite of ringbarking and clearing in many areas, and most of the state's building and constructional timber is obtained from it.

Mining.—The metalliferous areas of Queensland are concentrated in the metamorphosed zones of the Precambrian rocks of the northwest and the Paleozoic rocks of the northeast and southeast. With the gold rushes of the 1860s and 1880s gold production rose steadily from 2,738 fine oz. (worth £12,000) in 1860 to 676,027 fine oz. (£2,872,000) in 1900, but subsequent production declined. Production in the early 1960s was about 70,000 fine oz., valued at about A£1,000,000, mainly from Mt. Morgan and Cracow. The state's most extensive mineral workings are in the far northwest at Mt. Isa (copper, lead, silver, zinc) and Mary Kathleen (uranium) and at Mt. Morgan, 26 mi. (42 km.) southwest of Rockhampton (auriferous blister copper). In the early 1960s the average annual production was: copper 77,000 tons valued at A£22,500,000, uranium 800 tons (A£8,000,000), lead 54,000 tons (A£4,000,000), silver 5,000,000 fine oz. (A£2,000,000), and zinc 30,000 tons concentrates (A£2,500,000). Zircon, ilmenite, rutile, and monazite are extracted from south coast beach sands. Coal production in the early 1960s was about 2,700,000 tons (A£8,000,000), of which three-fifths came from the 55 collieries of the West Moreton fields near Ipswich. The Big Seam at Blair Athol is 70–80 ft. (21–24 m.) thick with only a thin (25–135 ft. [8–41 m.]) overburden; measured reserves of this seam alone amount to 112,000,000 tons. Open cuts at Callide and Kiangara-Moura (east-central Queensland) were developed after 1950, the latter exclusively for coal export shipments.

Manufacturing Industries.—Manufacturing expanded considerably after World War II, the number of factories increasing from just under 3,000 in the mid-1940s to nearly 6,000 in the early 1960s, and the net value of production from about A£29,100,000 to about A£165,000,000. The two major groups of factory industries are metalworking-engineering and food processing. A little more than half of the total production came from factories in metropolitan Brisbane, where industries range from shipbuilding (naval craft and cargo ships up to 10,000 tons), motor-vehicle assembly, and furniture manufacture to sugar refining, fruit canning, and brewing. Developments after World War II included a cotton-spinning mill and a tire factory. Two provincial cities are primarily industrial in function: Ipswich, with railway engineering shops and woolen mills; and Maryborough, with railway engineering, factories making sugar-mill and mining machinery, and a small shipyard. Railway workshops are also maintained at Rockhampton and Townsville, and Toowoomba and Dalby manufacture agricultural machinery and implements. The generation and supply of electric power has also become a major industry.

External Trade.—In the early 1960s the total value of Queensland's exports was about A£300,000,000, of which about A£125,000,000 went to other Australian states. The chief items of over-

seas exports were: wool, sugar, chilled and frozen beef and veal, canned meat, titanium and zircon concentrates, lead and silver-lead ores and bullion, copper ores and concentrates, and butter. Imports received directly from overseas consist largely of manufactured goods, the main items being motor vehicles and parts, machinery, hardware and metal manufactures, and oil.

State Finance.—As the federal government has the exclusive right to customs and excise duties and collects income taxation on behalf of the states, a substantial portion of the Queensland government's revenue is made up of payments by the commonwealth government. These amounted in the early 1960s to about A£60,000,000 annually, of which A£10,000,000 was specifically provided for highway construction and maintenance and just over A£1,000,000 for university requirements. Additional revenue amounted to about A£142,000,000, including approximately A£35,000,000 from the state railways and A£24,000,000 from state taxes and duties. State expenditure amounted to about A£200,000,000 annually, including approximately A£40,000,000 for the state railways and A£21,000,000 for education. Other major items of expenditure were roads and bridges, public health, the State Insurance Organization, housing development, and law and order.

Transport and Communications.—With a comparatively small population dispersed over a wide area and with a large volume of primary commodities needing transport over great distances the provision of adequate public transport facilities (rail, road, and air) has involved a high capital outlay in relation to returns. Standardization of the 3 ft. 6 in. gauge by the State Railway Department was primarily a device to enable maximum railway mileage to be constructed and operated at minimum cost; by 1924, when the Brisbane-Cairns coastal line was completed (1,043 mi.), the present system was substantially in operation, though the 80 mi. of standard-gauge (4 ft. 8½ in.) line from Brisbane to Kyogle was not completed until 1930. In the early 1960s rail mileage was about 6,000. Air-conditioned trains with diesel-electric power were introduced in the early 1950s on the four main lines: the Brisbane-Cairns ("Sunlander"); Brisbane-Cunnamulla ("Westlander"); Rockhampton-Winton ("Midlander"); and Townsville-Mount Isa ("Inlander") lines.

There is a network of interstate and internal air services, established by the commonwealth government's Trans-Australia Airlines, by Ansett-A.N.A. Airways Pty., Ltd., and by several smaller concerns. Regular services are operated to New Guinea and New Caledonia, and Brisbane is a port of call on regular international air services to Asia and Europe. Connections with other overseas air routes are made via Sydney and Darwin. Flying doctor aircraft are based at Charleville, Cloncurry, and Charters Towers.

There are about 121,000 mi. (194,700 km.) of roads in the state, including 8,250 mi. (13,280 km.) of state highways and 10,100 mi. (16,250 km.) of main roads. Passenger and cargo ships maintain regular services along the Queensland coast and to southern states, Thursday Island, and New Guinea, and Queensland ports are also served by overseas shipping lines.

QUEEN'S REGULATIONS: see MILITARY LAW.

QUEENSTOWN, a town in Cape Province, Republic of South Africa, lies 129 mi. (208 km.) NW of East London by road and 133 mi. (214 km.) by rail at 3,533 ft. (1,077 m.) above sea level. Pop.

(1960) 33,182, comprising 9,743 Europeans, 20,437 Bantu, 2,871 Coloureds, and 131 Asians. Proclaimed a township in 1853, Queenstown was laid out in an unusual hexagonal pattern with streets radiating from the then existing fort at the centre, so that, in the event of attack by marauding tribesmen, enflaming fire could be brought to bear from the fort. On the main street, Cathcart Road (named after the town's founder, Sir George Cathcart), is the town hall (1879), a dignified building with a clock tower, which was completely renovated in the mid-1950s. There are secondary schools, a technical high school, parks, a public library, a museum, and an art gallery. The many sporting facilities include a fully equipped municipal stadium. The administrative centre of the Cape midlands and the inland border territories, Queenstown lies on the national roads system and railway line connecting the Transvaal and Orange Free State with East London. There is an airfield near the town. The town is the centre of a prosperous cattle- and sheep-farming district. Local manufactures include agricultural machinery and furniture, and there are also engineering works, a creamery, grain mills, and a meat-canning factory.

(Hu. G. H.; A. H. WH.)

QUENTAL, ANTERO TARQUINIO DE (1842–1891), Portuguese poet and essayist, who played a prominent, enthusiastic, and lifelong part in the struggle to create a new outlook in literature and society, and to organize the working classes. His activities were interrupted by fits of acute depression arising from personal anxieties, or from intellectual and ideological crises, and in his poetry, especially in the sonnets, he gives outstanding aesthetic expression to both personal problems and philosophic themes. In the 109 sonnets of *Os Sonetos completos* (1886) the reader can follow Quental's spiritual evolution.

He was born on April 18, 1842, at Ponta Delgada in the Azores, of an aristocratic and illustrious family; among his forebears were writers and mystics, and he was brought up as a practising Catholic. While studying law at the University of Coimbra (1858–64) he was profoundly influenced by the new literary and ideological movements which were at that time gaining ground in intellectual circles. His romantic early poems, *Raios de extinta luz* (written 1859–63) and the delicate lyrics (written 1861–64) published as *Primaveras românticas* (1875), were soon replaced by the poems of *Odes modernas* (1865), which gave expression to the problems agitating him and his contemporaries. Their publication won him a remarkable intellectual and moral ascendancy among his fellow students. This prestige was shown, for example, on the occasion of the visit to Coimbra of Prince Umberto of Savoy (Humbert I of Italy) in Oct. 1862, when Quental addressed him on behalf of the undergraduates with a political audaciousness also revealed in the *Odes modernas*. He was prominently involved, too, in the famous literary polemic, known as the "Coimbra Question," which was started by his pamphlet, *Bom senso e bom gosto* ("Good Sense and Good Taste," 1865), in which he attacked the hidebound formalism of Portuguese writing as exemplified especially in the work of the poet António Feliciano de Castilho. His later pamphlet, *A dignidade das letras e as literaturas oficiais*, proclaimed his mission to create a new poetry which would be "the voice of the Revolution."

After graduating, and a visit to the Azores, Quental settled in Lisbon, and looked for employment in accord with his social ideals. He tried a job as a typographer, first in Lisbon and then (1867) in Paris, thus gaining firsthand acquaintance with working-class life. Six months of this experience, however, awakened him from his dream of becoming a modern social apostle, and disillusionment and ill-health forced him to return to Portugal. After a trip to the United States and Canada (1869), he went back to Lisbon, where he again tried to realize his ideals, taking an active part in propaganda on behalf of the workers and also working to reawaken Portuguese cultural life. In 1870, with his friend J. P. Oliveira Martins (*q.v.*), he founded a republican journal, *A República*, and also organized a group of writers, *O Cenáculo*, which prepared a famous and provocative series of lectures, the *Conferências democráticas do Casino*, given in 1871, aiming to make known in Portugal the main trends of modern thought. Influenced by the Socialist theories of Proudhon, he collaborated in

the attempt to organize the First International in Portugal, and edited the Socialist journal, *O Pensamento Social* (1872).

But, amid all this activity, Quental was troubled by increasing discontent. He felt within himself a struggle between two opposing forces, thought and will. The resultant spiritual anguish is splendidly expressed in some of his sonnets, which also reflect his reading of the German philosophers, especially Schopenhauer and Edouard von Hartmann. At this stage, he abandoned many cherished projects, and tore up his early poems and other writings. His health declined further, and, his illness proving difficult to diagnose, in 1877 he went to Paris to consult the neurologist, Jean Martin Charcot. Treatment gave temporary relief and during a period of renewed calm he wrote some of his last and finest sonnets.

In 1882 he retired to Vila do Conde, near Oporto, to supervise the upbringing of two orphan girls whom he had adopted. He continued to watch political developments, however, following with interest the experiments in government of Oliveira Martins. The crisis provoked by the British ultimatum of 1890 (see PORTUGAL: History) brought him back into politics, and he accepted the chairmanship of the *Liga Patriótica do Norte*, but resigned a few weeks later when the league broke up under the pressure of the rival political factions of which it was composed.

In 1891, Quental left Vila do Conde to visit his relations and properties in Ponta Delgada, but his contacts with his family proved strained. His nervous condition was thereby aggravated, and on Sept. 11, 1891, he shot himself.

As a philosopher, Quental opposed positivism, and moved, by way of Hegelian idealism, to acceptance of Schopenhauer's view of the universe, and of man's only possible escape from irrational suffering as being through quietism. He avoided Schopenhauer's pessimistic conclusion by stressing the importance of the individual conscience, and finally, he approached independently the position of Kierkegaard (whose work was unknown to him), and came to believe that by exploration of his own ego, man can attain union with God, who is the Ego of his ego, the Spirit of his spirit. Progress, he concluded, evolves not only through history, but through the individual, irrespective of material circumstances. The thoughts behind his struggle to find a solution to these problems were expressed in many of his sonnets and in his most important philosophical study, *Tendências gerais da filosofia na segunda metade do século XIX* (1889).

As a poet, Quental made few formal innovations, and his use of the sonnet, a classic form in Portuguese poetry, is traditional in imagery and vocabulary. Yet these formal limitations did not prevent him from giving direct, dramatic, and universal expression to the anxieties arising from the crisis in late 19th-century Western thought.

(F. DE D. C.)

QUERCIA, JACOPO DELLA (c. 1374–1438), one of the most original Italian sculptors of the early 15th century, was born, probably at Siena, between 1370 and 1374. In c. 1406 he carved the tomb of Ilaria del Carretto in the cathedral of Lucca, a town with which his father, the goldsmith and sculptor Pietro

d'Angelo, had long been associated. The effigy and sarcophagus from this tomb alone survive. In 1408 Quercia was employed at Ferrara on a statue of the Virgin and Child which still exists in the Museo dell' Opera del Duomo, and a year later he received the commission for the celebrated Fonte Gaia in the Campo at Siena (now replaced by a copy, original in the loggia of the Palazzo Pubblico). The scheme of this highly individual fountain was repeatedly modified, and effective work upon it seems to have been confined to the years 1414–19. Concurrently with the Fonte Gaia, Quercia was engaged on commissions at Lucca which included a statue of an apostle for the exterior of the cathedral (1413), the tomb slabs of Lorenzo Trenta and his wife in S. Frediano (1416) and the Trenta altar in the same church (1416–22). These are strongly northern in character. In 1417 Quercia agreed to undertake two gilt bronze reliefs for the baptismal font in S. Giovanni in Siena; the contract for one of these was later transferred to Donatello, but the second, "Zacharias in the Temple," was completed in 1430 and is still on the font. Between 1427 and 1430 he also designed the hexagonal tabernacle in the centre of the font and carved the reliefs of prophets in the niches with which five sides of it are filled. In 1425 he had signed a contract for the central doorway of S. Petronio at Bologna: work on this occupied him until his death on Oct. 20, 1438. In its present form the doorway consists of ten scenes from Genesis set in the pilasters at the sides, five scenes from the early life of Christ across the architrave and a lunette surrounded by reliefs of prophets containing statues of the Virgin and Child and SS.

Petronius and Ambrose (the latter an addition by Domenico da Varignana). The Genesis scenes are Quercia's most inspired and expressive works. In 1435 Quercia was appointed superintending architect of Siena cathedral for which he was employed on the decoration (unfinished) of the Cappella Casini. To the same late phase belongs the Vari-Bentivoglio monument in S. Giacomo Maggiore, Bologna (after 1433). Quercia also carved in wood, notably an Annunciation group in the Collegiata at San Gimignano (1421). Though his work is exceptionally fully documented, Quercia is a mysterious artist and his ambivalent style fits less easily than that of his more conventional contemporary Ghiberti into the context of Tuscan early Renaissance sculpture.

BIBLIOGRAPHY.—P. Bacci, *Jacopo della Quercia. Nuovi documenti e commenti* (1929); G. Nicco, *Jacopo della Quercia* (1934); L. Biagi, *Jacopo della Quercia* (1946). (J. W. P.-H.)

QUERCITRON BARK is the inner bark of *Quercus velutina*, the black oak, a native of the middle and southern United States. The exterior bark is removed from the tree by shaving and the inner portion, which contains a colouring matter, is detached and ground. The colouring matter of quercitron bark is quercitrin, $C_{21}H_{22}O_{12} \cdot H_2O$, a glycoside which by hydrolysis with acid yields quercetin, $C_{15}H_{10}O_7$, and the sugar rhamnose, $C_6H_{12}O_5$. When quercitron bark is exhausted with hot water under pressure, the extract deposits a crude quercitrin which is known commercially as yellow flavine. A second variety known as red flavine, prepared by digesting an extract of the bark at the boil with dilute acid, is in reality a crude quercetin. These products dye wool mordanted with aluminum and tin bright yellow and orange shades; they were at one time used with cochineal for obtaining especially vivid scarlets. (A. G. P.)

QUERCY, an ancient *pays* or district of southwestern France, corresponding, in terms of modern *départements*, to the greater

part of Lot and part of Tarn-et-Garonne (*qq.v.*). Cahors (*q.v.*) and Figeac were the chief towns of Haut or Upper Quercy, Montauban (*q.v.*) and Moissac those of Bas or Lower Quercy.

In Gallo-Roman times the district was organized as the *civitas* or community of the Cadurci, a Celtic people whose name is reflected in those of Cahors and Quercy alike. Occupied by the Visigoths in the 5th century A.D., Quercy was taken by the Franks in the 6th. It was part of Carolingian Aquitaine in the first half of the 9th century, but soon came into the possession of the counts of Toulouse. Louis VIII of France, however, accepted homage for northern Quercy from the bishop of Cahors, Guillaume de Cardaillac, in 1223; and the south was included in the possessions of Alphonse of Poitiers and Toulouse. The Anglo-French Treaty of Paris (1259), which accorded to the English king some ill-specified rights within the diocese of Cahors and a conditional claim on the western areas of Alphonse's territory, made Quercy a subject of dispute, first diplomatic and then military, between France and England (*see also* GUIENNE). By the Treaty of Brétigny in 1360 France ceded Quercy to the English, but they were finally expelled in 1443, during the last phase of the Hundred Years' War. Quercy was subsequently made part of the French *gouvernement* of Guienne.

In the 16th-century Wars of Religion, Quercy was savagely contested between Catholics and Huguenots; and in the 1620s Montauban was a major centre of Huguenot resistance. The *généralité* of Montauban, under an intendant (*q.v.*), was instituted in 1635.

QUERÉTARO, a central plateau state of Mexico. Pop. (1960) 355,045; area 4,544 sq.mi. (11,769 sq.km.). On the semiarid mesa and traversed at the north by a spur of the Sierra Madre known as the Sierra Gorda, Querétaro is about evenly divided between mountainous mineralized areas and the rolling plains and fertile valleys of the south which form part of Mexico's granary or *bajío*. The state has good air connections and is traversed in a southeasterly direction by the trunk highway from Nogales to Mexico City and the National Railways of Mexico. The climate is generally dry and temperate except in the northwest portion which is hot. Rainfall is moderate and frosts are few and light.

With soil 10 to 15 ft. (3 to 5 m.) deep in the southern lowlands, the state produces a large variety of crops: fruits, grain, medicinal plants, and a notable sweet potato or *camote*. Though deposits of gold, copper, lead, tin, and other metals occur, the chief products are opals and mercury, especially in a compound (sulfoselenide of mercury) known as onofrite, from Cerro San Onofre. The breeding of fighting bulls is also an important activity.

The area was inhabited by the Otomi-Chichimec Indians who were conquered by the Spaniards in 1531. Colonization took place in the 1550s and Querétaro was administered with Guanajuato before it became a state in 1824. (J. A. Cw.)

QUERÉTARO, a city of Mexico and the capital of the state of Querétaro, is 167 mi. (269 km.) by rail and 162 mi. (261 km.) by highway NW of Mexico City, and located at the foot of the Cerro de las Campanas. Elevation 6,168 ft. (1,880 m.); pop. (1960) 67,674. Querétaro is considered an excellent example of a Spanish colonial city. It was founded by the Otomi Indians and was incorporated into the Aztec empire in 1446 and henceforth served as an outpost against the warlike tribes to the north until it was brought under Spanish control in 1531. Throughout most of the colonial period Querétaro was important primarily as a way station and supply centre serving the rich mining districts of Guanajuato and Zacatecas. Colonial buildings include the cathedral (restored several times), the federal palace and the churches of Santa Rosa, Santa Clara, and San Agustín. Water is brought to the city by an aqueduct (built 1726–38) approximately 5 mi. (8 km.) long, with 74 arches, 50 ft. (15 m.) high and upborne by piers 46 ft. (14 m.) thick. The main products are textiles, pottery, and agricultural produce. The city has one of the largest and oldest cotton factories in Mexico.

Querétaro has witnessed many fundamental changes in the evolution of modern Mexico. In 1810 it was the scene of a plot against Spain which led to the uprising headed by Miguel Hidalgo y Costilla in September of that year. In 1848 the Treaty of Guadalupe

LOUVRE, PARIS

Hidalgo terminating the U.S.-Mexican War was signed there. The forces of Benito Juárez defeated those of Emperor Maximilian at Querétaro in 1867; and on a nearby hill Maximilian and his generals Miguel Miramón and Tomás Mejía faced the firing squads. The Mexican constitution of 1917 was written in Querétaro which was also the birthplace of the National Revolutionary Party of Mexico (1929), the dominant political force in the republic.

(J. J. J.)

QUESNAY, FRANÇOIS (1694–1774), French economist and leader of the first systematic school of political economy (see *PHYSIOCRATIC SCHOOL*), was born, perhaps at Méré, near Paris, on June 4, 1694. He studied surgery, graduated as a doctor of medicine (1744) and eventually became consulting physician to Louis XV. He did not publish anything on economics until the age of 60 and then mainly anonymous articles. But at Versailles, where he enjoyed the support of Mme de Pompadour, there gathered around him and Jean C. M. V. de Gournay (1712–59) the *secte des économistes*, notably Victor Riqueti de Mirabeau, Nicolas Baudeau, P. P. le Mercier de la Rivière, G. F. le Trosne, and P. S. du Pont de Nemours, who looked to Quesnay as their leader and enthusiastically propagated his doctrines. A. R. J. Turgot was also associated with the group; Adam Smith got to know Quesnay and had a great respect for his ideas. Quesnay died at Versailles on Dec. 16, 1774.

Quesnay's peculiarities of expression and his extreme emphasis on agriculture as the sole economically productive activity yielding a *produit net*, as contrasted with the "sterility" of industry and commerce, should not be allowed to conceal the great importance of his contributions to economic thought. He contributed, above all, to that systematization of economic analysis which introduced the classical period in Britain and France; only Richard Cantillon, who published *Essai sur la nature du commerce* in 1755, preceded him in this. Quesnay's system was summed up in his *Tableau économique* (1758), which displayed diagrammatically the interdependence of the different economic classes and sectors and the flow of payments among them. In his *Tableau* Quesnay developed the assumption of a state of stationary economic equilibrium, a fundamental simplifying concept from which so much subsequent economic analysis departed. The general equilibrium analysis of Léon Walras and the input-output analysis of modern economics developed by W. W. Leontief are descendants of Quesnay's *Tableau*. Especially important was his analysis of capital as *avances*, or a stock of wealth which had to be accumulated in advance of production, and his classification of these *avances* in a manner which developed the distinction between fixed and circulating capital. Quesnay's analysis of savings as possibly harmful in that uninvested savings may disturb the equilibrium of the flow of payments is similar to that of J. M. Keynes. However, Quesnay's ideas on saving were supplanted in orthodox economic thought for a century or more by the theory of Turgot and Smith, according to which saving is unconditionally beneficial.

The methodology of Quesnay's system and his principles of policy started from an extreme form of the doctrine of natural law which led him to proclaim that *laissez faire* in economics—plus the single tax on net income from land—represented the divinely appointed economic order. Quesnay, in fact, was one of the originators of 19th-century doctrines of the harmony of class interests and of the related doctrine that the maximum social satisfaction occurs under free competition. He also developed the *a priori* method, often employed subsequently, of attempting to demonstrate these doctrines. In their day his principles of policy represented an active campaign against monopolies and privilege, requiring a strong government based, as Quesnay advocated, on a powerful monarchy.

Quesnay's *Oeuvres économiques et philosophiques* were edited by A. Oncken (1888).

See M. Beer, *An Inquiry Into Physiocracy* (1939); J. A. Schumpeter, *History of Economic Analysis*, pp. 223–243 (1954). (T. W. H.)

QUESNEL, PASQUIER (1634–1719), French Jansenist theologian and author of the *Réflexions morales*, leader of the Jansenist party after the death of Antoine Arnauld, was born in Paris on July 14, 1634, and joined the French Oratory in 1657.

His Jansenist sympathies led to his banishment from Paris in 1681, and three years later he was expelled from the Oratory. Fearing further measures of persecution, he fled to Brussels where he lived with Arnauld. In 1703 he was arrested, but soon escaped to Amsterdam, where he lived until his death on Dec. 2, 1719.

Quesnel's *Nouveau Testament en français avec des réflexions morales* (1692) played almost as large a part in the literature of Jansenism as Jansen's *Augustinus*. The bull *Unigenitus* (1713) condemned 101 sentences from the *Réflexions morales*. Quesnel, who had never admitted that his opinions were heretical, received the last sacrament on his deathbed. See also *JANSENISM*.

See A. Le Roy's edition of Quesnel's correspondence, 2 vol. (1900); A. Vacant, *Dictionnaire de théologie catholique*, vol. xiii, col. 1460–1535 (1937). (N. J. A.)

QUÉTELET, (LAMBERT) ADOLPHE (JACQUES) (1796–1874), Belgian mathematician, astronomer, and statistician, known for his work on census taking and the application of statistics and the theory of probability to social phenomena, was born in Ghent on Feb. 22, 1796. He studied astronomy at the Paris Observatory and the theory of probability under Pierre Simon Laplace. He lectured at the Brussels athenaeum, military college, and museum; became head and founder in 1828 of the Royal Observatory; and perpetual secretary (1834–74) of the Royal Academy. He made important contributions to the study of meteoric showers.

Quêtelet was a prime mover in the development of methods for simultaneous observations of astronomical, meteorological, and geodetic phenomena at scattered points throughout Europe. His outstanding contributions to statistical organization and practice included many aspects of governmental statistics, notably census taking; organization of the first international statistical conference; the development of uniformity and comparability in international statistics; and the application of probability theory to anthropology and sociology. His *Sur l'homme* (1835) developed the concept of the "average man" as the central value about which measurements of a human trait are grouped according to the normal probability curve. His studies of the numerical constancy of such voluntary acts as crimes stimulated extensive studies in "moral statistics" and wide discussion of free will versus social determinism in human behaviour. He died on Feb. 17, 1874, in Brussels. (F. H. Hs.)

QUETTA, a city in West Pakistan, formerly capital of Baluchistan (*q.v.*), now the headquarters of the Quetta-Pishin District and of Quetta Division, lies 536 mi. (863 km.) N of Karachi by rail. Pop. (1961) 106,633, including the cantonment. It rose to prominence in 1876, when Sir Robert Sandeman founded a residency there. The name Quetta (Kawatah) is a variation of the word *kwatkot*, signifying a fortress, and the town is still locally known by its ancient name of Shal or Shalkot. The cantonment and civil station of Quetta stand in an open plain about 5,500 ft. (1,676 m.) above sea level, within a ring of mountains (such as Takatu, Murdar Ghar, and Chiltan), which overlook it from a height of more than 11,000 ft. (about 3,400 m.). North of Quetta is the open plain leading to Pishin. The defensive works, stretching from the base of Takatu to the foot of the Mashelakh Range on the west, bar the way to advance from the Khojak Pass, which leads through the Bolan Pass to Sibi. During the last quarter of the 19th century Quetta grew from a dilapidated group of mud buildings, with an inferior bazaar and a few scattered remnants of neglected orchard cultivation, into a well-laid-out and widespread town and cantonment and a strongly garrisoned army station. The Staff College was opened there in 1907. Jinnah Road is the principal bazaar. There are two government colleges and a technical school. Sandeman Library has existed since 1885 and a geophysical institute was established in the early 1960s.

Quetta is a market for western Afghanistan, eastern Iran, and much of central Asia, and its population had grown to 83,892 by 1951, despite a disastrous earthquake which practically destroyed the city on May 31, 1935, with the loss of between 20,000 and 40,000 lives. Its importance as a summer resort increased after the establishment of Pakistan.

Quetta is the southernmost point in the line of frontier posts

QUETZALCOATL ("Plumed Serpent"), first worshiped in central Mexico possibly starting with the pre-Classical period (before c. A.D. 300), was god of the wind and of the dawn, identified with the planet Venus, the light, and the colour white. He symbolized wisdom and knowledge, and he was regarded as god of life and fertility, inventor of agricultural processes, patron of arts and

As a poet, Quevedo is supreme. His large output ranges from verse in the cant of the underworld through lampoons and parodies to meditative poems on time and death. His love poetry includes both poems showing an obsession akin to disgust with the crudely physical, and sonnets that transform the conventional Petrarchan tradition by their intensity of feeling. The keynote is his feeling that the divine calls the mind to a love which is torture to the

body, that passion shows the light of life while consuming itself in darkness. There is no sensuous prettiness or emotional softness in Quevedo's poetry: his intense feeling is conveyed with dignity of expression and intellectual strength.

Though an opponent of the Latinizing innovations introduced by Luis de Góngora, whom he parodied unmercifully, Quevedo was adept in the new Baroque style. The greatest exponent of *conceptismo* (see SPANISH LITERATURE), he shows as masterly a use of the metaphysical conceit as does John Donne. In his satires his linguistic ingenuity and audacity are unbounded, and as a virtuoso of language he is unequaled in Spanish literature. The *Sueños* (1627), mostly visions of hell written at intervals from 1606 to 1622, show his development in the technique of satire: the conceits grow from mere puns into scintillating images that transpose the identities of objects and invert their functions. This culminates in his masterpiece, *La hora de todos* (written 1635-36). Here transposition and inversion produce a picture of a world where commercialism, imperialism, racialism, slavery and international politics have turned values inside out. No less masterly is the picaresque novel, *La vida del Buscón* (1626). Its verbal wit and often grotesque exaggeration have tended to obscure the acuteness of its psychological insight: the son of disreputable parents, the protagonist carries a burden of shame and guilt from which he seeks escape in illusory fantasies that lead to a life of roguery and deception.

In his nonsatirical work, Quevedo's *conceptismo* produces a terse and dignified style. His precision in the association of disparate concepts gives, in such works as *La política de Dios* (I, 1626; II, written 1634-35) and *La providencia de Dios* (written 1641), an original and powerful expression to a thought that is mainly conservative and traditional. His *Marco Bruto* (1644) is an interesting defense of monarchy against democracy. For Quevedo social and political issues resolve themselves into questions of personal morality. This made him promulgate in Spain the Stoic doctrines which Justus Lipsius had popularized throughout Europe. He translated Phocylides, Epictetus and Seneca and wrote Stoic treatises of his own of which the chief are *La cuna y la sepultura* (1634) and *Virtud militante* (written 1634-36). Their originality consists in presenting the subject in terms of the 17th-century preoccupation with the paradoxes of human nature and life. Quevedo's Stoicism is neither priggishness nor indifference, but a concern for one's own integrity that does not exclude compassion for one's neighbour, but does exclude the desire to judge, rebuke and punish him.

QUEZALTENANGO is a department in western Guatemala. Its surface elevations range from near sea level to more than 12,000 ft. (3,658 m.) at the peak of the volcano Santa María; its mountain valleys lie at altitudes of about 8,000 ft. (2,438 m.). It has some industry and a diversified agricultural production which includes grains, coffee, bananas, and livestock. Area 753 sq.mi. (1,950 sq.km.). Pop. (1964) 267,962, chiefly Indian or mestizo descendants of pre-Conquest Quiché stock.

The capital city Quezaltenango (pop. [1964] 56,921 [mun.]), the second city of the republic, is connected with Guatemala city by paved highway and air transportation. It stands at the foot of the volcano Santa María near the site of the battle in which the Spaniards under Pedro de Alvarado and their Indian allies from Mexico decisively defeated the native Quichés in 1524. Before the conquest it had been the capital of a Quiché kingdom known as Xelajú. It is a marketing and processing centre important for textile factories, mills, and breweries, and the seat of two university faculties.

An electrified railway, built in 1930 to connect with the coastal line, ceased operation in 1933 after extensive flood damage, but

the Santa María hydroelectric plant continued to operate and in the early 1960s was capable of supplying power in excess of demand.

The name Quezaltenango means "palace of the quetzal," a native bird which had great symbolic importance among the Mayas and is now the national symbol of Guatemala. (W. J. G.)

QUEZON, a long narrow coastal province of Luzon Island, Philippines, is 270 mi. (435 km.) long and varies from 5 to 35 mi. (8 to 56 km.) in width. Area 4,609 sq.mi. (11,937 sq.km.). Formerly called Tayabas, the name was changed in 1946 in memory of Pres. Manuel Luis Quezon y Molina. The northern two-thirds of the province is mountainous and sparsely inhabited but excellent cabinet and plywood timber is produced near Infanta and Baler. Southern Quezon contains some of the largest coconut plantations in the world. Provincial population (1960) 653,426. Lucena, on Tayabas Bay, is the capital and major copra centre; Tayabas, 8 mi. (13 km.) N of Lucena, is also a trading and copra centre.

(R. E. He.)

QUEZON CITY, capital city of the Republic of the Philippines named for Pres. Manuel Luis Quezon y Molina, is located immediately east of Manila on Luzon. Pop. (1960) 397,990. Much of the city lies at an elevation about 100 ft. (30 m.) above downtown Manila, which is slightly above sea level. Temperatures are lower than in Manila; because Quezon is farther from the bay, humidity is lower.

The city of Quezon officially replaced Manila as the Philippine capital in 1948 and in the second half of the 20th century construction of government buildings was underway. Most functions of the national government, however, remained in Manila. The University of the Philippines is located in Quezon as well as Ateneo de Manila and a veterans' hospital. The city is bisected by the Circumferential Highway along which light industry began to develop.

San Francisco del Monte and Kamuning are first-class residential sections, while the Cubao section is an important transportation junction and bazaar area. (R. E. He.)

QUEZON Y MOLINA, MANUEL LUIS (1878-1944), one of the leaders of the Philippine independence movement and first president of the Philippine Commonwealth, was born Aug. 19, 1878, at Baler, Tayabas Province (renamed Quezon Province in 1946), on the island of Luzon. He joined the insurrectionist movement of Emilio Aguinaldo (*q.v.*) but later swore allegiance to the territorial administration. He was a member of the Philippine Assembly (1907-09), resident commissioner to the United States (1909-16), and president of the Philippine Senate (1916-35). As a fiery nationalist leader, he worked for the passage of the Philippine Commonwealth and Independence Act (Tydings-McDuffie Act) in 1934, and he was elected the first president of the Philippine Commonwealth in 1935. In that office he launched his program for "social justice" in the interest of the peasants and the urban labourers, promoted commerce and industry, undertook a new defense program for the Philippines, and began the construction of a new national capital in Quezon City in the suburbs of Manila. After Japan attacked and occupied the Philippines, Quezon went to the United States. On behalf of the Philippines he signed the Declaration of the United Nations against the fascist nations and became a member of the Pacific War Council in 1942. He worked on plans for rehabilitation of the Philippines and wrote his autobiography entitled *The Good Fight*. Quezon died of tuberculosis at Saranac Lake, N.Y., on Aug. 1, 1944. (C. A. B.)

QUIBERON BAY, BATTLE OF, was fought between an English and a French fleet on Nov. 20, 1759, in Quiberon Bay, south of Lorient, France, during the Seven Years' War. The English victory put an end to French plans to invade Great Britain. In 1759 the duc de Choiseul ordered concentrations of troops in Flanders and Brittany and the conjunction of the Brest and Toulon fleets to cover their passage. On Aug. 5, 1759, the Toulon fleet under Adm. de la Clue slipped out of port but was caught by Adm. Edward Boscawen off Lagos, Port., and defeated on Aug. 18-19. Adm. Sir Edward Hawke (*q.v.*) had meanwhile maintained a close blockade on Brest and on the French transport ships in the Morbihan, the landlocked waters of Quiberon Bay, but on Nov. 9

bad weather forced him to run into Torbay, Devon. He was able to leave port again on Nov. 14, and on the same day the Brest fleet under the comte de Conflans put to sea, having learned of Hawke's withdrawal. Conflans headed south for Quiberon Bay, followed by Hawke. At dawn on Nov. 20 both fleets were about 30 mi. west of Belle-Île, opposite the bay, though still out of sight of each other. Conflans stood in close to attack a British squadron of frigates under Commodore Robert Duff, which was blockading Quiberon, but on sighting Hawke to the northwest, Conflans ordered his fleet to close up and run into the bay. He hoped that the shoals, lack of pilots, and a northwesterly gale blowing on a lee shore would discourage Hawke's pursuit. Conflans had 21 ships of the line and Hawke 23, with Duff's squadron of frigates.

At 9:45 A.M. on Nov. 20, receiving confirmation that it was the French fleet, Hawke ordered a "general chase." At 2:30 P.M. the British van engaged the French rear to the south of Belle-Île and soon afterward the fleets swept between the Cardinal rocks and the Four sandbank into Quiberon Bay. A fierce battle followed before nightfall at 5:30 P.M., by which time two French ships had struck their colours and two others had been sunk. During the night nine French ships escaped south to Rochefort, one sinking on the way. On Nov. 21, two ran ashore and were burned the next day, and the remaining seven escaped across the bar of the Vilaine River, where four broke their backs. The British lost two ships which ran aground and were burned. The battle, one of the decisive naval battles of the century, inspired David Garrick's song "Hearts of Oak."

See J. Corbett, *England in the Seven Years' War*, vol. II (1907); G. Marcus, *Quiberon Bay* (1960).

QUICHÉ is a Mayan language spoken in the 1960s by about 275,000 Indians in the western highlands departments of Quiché, Quetzaltenango, Totonicapán, Retalhuleu, and Sacatepéquez of Guatemala. Quiché, Cakchiquel (*q.v.*), and Tzutuhil (or Zutuhil; *q.v.*) make up the Quichean family of languages, all of which are confined to Guatemala.

The Quiché-speaking Indians live in villages, each having its own blend of the broadly similar culture and social organization common to highland Indians. The culture is a mixture of pre-Conquest, Spanish colonial, and modern elements, worked into a local variety by each community. Each has its own hierarchy of civil and religious officials, its own patron saint, and an economic specialty. Details of costume, speech, and custom vary from one community to another, but all depend primarily on small-plot agriculture, carried on without draft animals, plows, or the wheel. Most communities have supplementary occupations: in Totonicapán they are potters and woodworkers; those of Chichicastenango are lumber producers; in Cantel many work in a modern cotton mill; and near coffee plantations many work as field peons. The communities vary in size from a few hundred up to the largest, Chichicastenango, with a population of 30,000.

When the territory was conquered in 1524 by Pedro de Alvarado, the people apparently were more highly integrated politically than they are now. Alvarado defeated a large army of Quiché and other Indian allies on the plains of Xelajú, just outside modern Quetzaltenango, in a battle so sanguinary that the river running through the plains is still called the "river of blood." Today, in many communities, masked dancers reenact in a *baile de conquista* the battle and the death of their leader, Tecum Uman.

Archaeological remains in Quiché territory show large population centres before the Conquest and indicate several social classes. The ruins do not approach those of the Northern Maya in artistic achievement, but these Southern Maya had achieved higher levels of political organization. With the Conquest the Quiché class system was eliminated. Present-day communities are the result of regrouping under Spanish conquerors and under Guatemalan national programs. They show no recall of ancient glories or pre-Conquest times, nor do they exhibit pan-Quiché feeling.

History and legend are preserved in the *Popol Vuh*, written shortly after the Conquest; it relates legendary magical beginnings and wanderings that led the Quiché to Guatemala. It is a chronicle of kings and of wars they fought among themselves or with neighbouring principalities. The pre-Conquest Quiché shared

in the development of an intricate and accurate Mayan calendar marking the changing disposition of heavenly forces toward human beings. Pre-Conquest life was oriented to religion and politics and attained little technological development.

Present-day Quiché loyalties tend to be local rather than national. Though legally Guatemalan citizens, they participate little in national life and, along with other Indians of the highlands, form the poorest segment of society there. All the Indians are nominal Christians, mostly Catholic, with some Protestant converts. Each community is built around a central plaza on which face the church, the city hall, and the school.

Like other Guatemalan highlands Indians, Quiché-speakers have shown a steady increase in population; the rate of absorption into Guatemalan society is more than offset by local birthrate. See also MAYA INDIANS.

QUICHERAT, JULES ÉTIENNE JOSEPH (1814–1882), French historian and archaeologist, whose work was an important contribution to medieval studies in the 19th century, was born in Paris on Oct. 13, 1814. He was educated at the Collège of Ste. Barbe and completed his studies at the École des Chartes in 1835. After a period at the Bibliothèque Royale he was appointed professor at the École des Chartes in 1849 and later became its director. He died in Paris on April 8, 1882.

His first published study was *Recherches sur le chroniqueur Jean Castel* (1840), but it was his *Procès de condamnation et de réhabilitation de Jeanne d'Arc*, five volumes (1841–49), followed by *Aperçus nouveaux sur l'histoire de Jeanne d'Arc* (1850), which drew attention to his skilful marshaling of his original research. This was followed by a study and an edition of the writings of Thomas Basin, bishop of Lisieux (five volumes; 1855–60). Quicherat published many essays in contemporary reviews and the posthumous publication of *Mélanges d'archéologie et d'histoire* (two volumes; 1855–60) was a memorial to his wide and painstaking erudition. (H. G. WH.)

QUICKSAND, a state in which saturated sand loses its supporting capacity and acquires the character of a liquid. Once considered, especially by construction men, to be a special type of sand, quicksand is now recognized as a condition that may be assumed by any sand if its effective weight is temporarily or permanently carried by interstitial water. Some natural sands are in a condition so loose that minor disturbances caused by a foot-step may collapse the loose structure and produce a "quick" condition. Under these circumstances a person may become engulfed as in a fluid, but since the density of the sand-water suspension exceeds that of the human body, the body cannot sink. Struggling may lead to loss of balance and drowning. This possibility has no doubt led to the superstition, prevalent in literature, that quicksand has the ability to draw a person to his death. See SOIL MECHANICS. (R. B. P.)

QUIETISM, a doctrine of Christian perfection which disturbed the Roman Catholic Church, particularly in Italy and France, in the 17th century and was condemned as a heresy. Quietism, in general, holds that perfection consists in passivity (quiet) of the soul, in the suppression of human effort so that divine action may have full play. Quietistic elements have been discerned in Buddhism, Gnosticism, Manichaeism, in the teachings of the medieval Brethren of the Free Spirit, in the Spanish Alumbados, and even in certain doctrines of Martin Luther. But Quietism is, strictly speaking, the doctrine of Miguel de Molinos (*q.v.*), according to whom the way of Christian perfection is the interior way of contemplation to which anyone with divine assistance can attain and which can last for years, even for a lifetime.

Contemplation for Molinos was a vague, undetermined view of God which inhibits man's interior powers. The soul remains in dark faith, excludes all definite thought, and abstains from all interior action. To wish to act is an offense against God, who desires to do everything in us. Inactivity brings the soul back to its

principle, the divine being, into which it is transformed. God, the sole reality, lives and reigns in the souls of those who have undergone this mystic death. They can will only what God wills, because their own wills have been taken away. They should not be concerned about salvation, perfection, or anything else, but must leave all to God. It is not necessary for them to perform the ordinary exercises of piety. Since they worship God in spirit and in truth, they must exclude the use of all pictures and images. In temptation the contemplative should remain passive. He neither consents nor, by making acts of virtue, resists. The devil, indeed, can make himself master of the contemplative's body and force him to perform acts which seem exteriorly to be sins. But they are not. Indeed, this violence of the devil is an efficacious means of attaining to humility and contempt of self.

Molinos went to Rome in 1663 and soon won a reputation as a spiritual director of unusual ability: lay men and women, religious women, priests, even prelates were greatly impressed by his teaching. In 1675 he published his *Gula Espiritual*, which was approved by leading theologians and soon translated into a number of languages. When some priests who considered the *Spiritual Guide* a dangerous book wrote against it, their works were forbidden by the authorities. Soon, however, pernicious consequences of Molinos' doctrine began to manifest themselves, and in 1685 he was arrested by the papal police. Some 20,000 of his letters were examined. He himself and numerous other witnesses were interrogated with the result that 68 propositions embodying his system were condemned by Innocent XI in the bull *Coelestis Pastor* of Nov. 19, 1687. Molinos, who renounced his errors, was sentenced to life imprisonment. Cardinal Pier Matteo Petrucci, who had defended him, was obliged to recant.

Quietism was perhaps paralleled among Protestants by some of the tenets of the Pietists and Quakers (see PIETISM; FRIENDS, SOCIETY OF). It is certain, at any rate, that after the condemnation of Molinos a milder form of Quietism appeared in France, propagated by Mme Guyon (see GUYON, JEANNE MARIE BOUVIER DE LA MOTTE). She was influenced by the priest François Lacombe and in turn influenced him. When he was imprisoned in 1687 under suspicion of Quietism, Mme Guyon won the sympathy of Mme de Maintenon, the favourite of Louis XIV, and of François de Salignac de la Mothe Fénelon (q.v.), archbishop of Cambrai. The latter developed a doctrine of pure love sometimes called Semi-Quietism, which was condemned by Innocent XII in 1699. Both Fénelon and Mme Guyon submitted. This condemnation has often been looked upon as a blow at true as well as false mysticism and has been attributed to the narrow-mindedness of J. B. Bossuet.

See R. A. Knox, *Enthusiasm*, pp. 231-255 (1950). (E. A. R.)

QUILLER-COUCH, SIR ARTHUR THOMAS (1863-

1944), English writer (pseudonym "Q"), best remembered for his anthology *The Oxford Book of English Verse*, was born at Bodmin, Cornwall, on Nov. 21, 1863. He was educated at Newton Abbot College, Clifton College, and Trinity College, Oxford, where he was afterward appointed lecturer in classics (1886-87). *Dead Man's Rock* (1887), a romance in the style of R. L. Stevenson, was the first of a score of novels from only a few of which Cornwall and the sea are absent. From 1887 to 1892 he worked in London for a publishing firm and as assistant editor of *The Speaker*. A number of short stories which he contributed to this were reprinted in book form as *Noughts and Crosses* (1898), the first and best of a dozen similar volumes. In

1892 he settled at Fowey, the small Cornish port which appears in his stories as "Troy Town." Here he continued to write fiction and other prose, and also compiled several anthologies, such as *The Oxford Book of English Verse 1250-1900* (1900, revised 1939) and *The Oxford Book of Ballads* (1910). He was knighted in 1910 and in 1912 was appointed King Edward VII Professor of English Literature at Cambridge and also elected a fellow of Jesus College. His highly popular lectures were published in book form as *On the Art of Writing* (1916), *Shakespeare's Workmanship* (1918), *Studies in Literature* (3 series: 1918, 1922, 1929), *On the Art of Reading* (1920), *Charles Dickens and Other Victorians* (1925), and *The Poet as Citizen and Other Papers* (1934). Most of his serious verse is collected in *Poems* (1930) and his light verse in *Green Bays* (1930). He died at Fowey on May 12, 1944.

One of the most versatile and prolific writers of his time, "Q" was essentially a romantic. His chief contribution to letters was his clear and apparently effortless style. It reflects the personality of its author—neat, thorough, colourful, unhurried, hospitable, humorous, and chivalrous.

See *Memories and Opinions, an Unfinished Autobiography*, by "Q" (1944); F. Brittain, *Arthur Quiller-Couch* (1947). (Fk. Bn.)

QUILLWORK, embroidery work done with quills of the porcupine or, sometimes, those of bird feathers. This type of

BY COURTESY OF THE MUSEUM OF THE AMERICAN INDIAN, HEYNE FOUNDATION
QUILLED BUCKSKIN, ABOUT 17 IN. WIDE, USED AS ORNAMENTATION FOR A BABY CARRIER

decoration was used by American Indians from Maine to Virginia and westward to the Rocky Mountains. For all practical purposes the art has died out. Quills seem to have been an article of barter; hence their use was not confined to the natural habitat of porcupines. Quills were used on tobacco and tinder bags, workbags, knife and paintstick cases, cradles, amulets, burden straps, tunics, shirts, leggings, belts, moccasins, arm and leg bands, robes, horse trappings, and birchbark containers.

The gathering of raw materials—the hunting of porcupines or birds—was the duty of the men, who in some tribes also prepared the dyes. Sorting and colouring the quills, tracing the design on dressed skin or birchbark, and the embroidering were the work of women.

Dyes were compounded of roots, whole plants, and buds and bark of trees. The natural colour of quills was white, with red, yellow, green, blue, and black being produced by steeping in solutions of the plant materials. No variegated hues were made and rarely more than one shade of a colour. Patterns were stenciled or drawn with a bone paintbrush, stick, or dull knife, on the skin or bark that was to be worked. Although a cut stencil was usually used, a woman who was adept at drawing might copy a design free hand, making just a few measurements beforehand. Some even composed designs, both in form and colour, and worked them out as they embroidered. All designs were made up of wide or narrow lines, each composed of a series of close stitches. The decorations put on men's garb were generally related to their work, hunting and war, while figures worked on children's garments were usually symbolic and expressed prayers for safety, long life, and pros-

perity. There was considerable borrowing of designs, and figures that were sacred symbols in some tribes came to be purely ornamental in others. (A. S. L.)

QUILMES, Argentine city and suburb of greater Buenos Aires, 12 mi. (19 km.) SE of the federal district on the estuary of the Río de la Plata. Pop. (1960) 318,144. The Indians who gave the city its name were subdued and settled in the area by the Spanish in 1666. During the early 19th century it was twice the scene of hostilities: in 1806 when the first English invasion landed on its shores, and in 1827 when Argentine forces defeated the Brazilian fleet in the estuary. Quilmes is one of the important industrial centres of Buenos Aires and the location of large breweries and distilleries. (Js. R. S.)

QUILON, a town and district of Kerala, India. The town, headquarters of the district, lies 471 mi. (760 km.) S of Madras and 45 mi. (72 km.) N of Trivandrum. Pop. (1961) 91,018. It is one of the oldest ports of the Malabar Coast (*q.v.*) and variously known as the Elancon of the early travelers, Kaulam Mall of the Arabs, and Coilum of Marco Polo. It stands on Ashtamudi Lake, a backwater with eight creeks. Its site, commanding the navigation of the large backwater system, made it commercially important; the Portuguese had a factory there, which was captured by the Dutch in 1662 and later passed to the British. The Thevally Palace of the former maharaja of Travancore, with an array of leaning coconut palms, is a notable beauty spot.

The spinning and weaving of coir and cotton, the manufacture of tiles, and the hulling of cashew nuts (mainly imported from East Africa) are the chief industries. The town is a large educational centre with three colleges, one of which is managed by the Roman Catholics and the other two by a trust of the Ezhava sect (toddy tappers), all affiliated with Kerala University. A metre-gauge railway links it northward with Ernakulam, and another route southward with Trivandrum and eastward with Shencottah.

QUILON DISTRICT has an area of 1,944 sq.mi. (5,035 sq.km.) and a population (1961) of 1,941,228. (G. Kn.)

QUILTING, the process of stitching together several layers of fabric, usually with some soft, thick substance placed between them. The layer of wool, cotton, or other stuffing provides insulation; the stitching keeps the stuffing evenly distributed and also provides opportunity for artistic expression in both design and execution. Quilting has long been used for clothing and other purposes in many parts of the world, especially in the Far East, India, Iran, the Middle East, and in the Muslim regions of Africa. It was also used for military doublets worn under armour, and quilted articles sometimes provided a less expensive substitute for armour (*see* ARMOUR, BODY). Quilting, particularly of bedcovers (quilts), reached the status of a minor art in Europe in the 14th century and from there was carried to North America, where it reached its greatest development in the period from the middle of the 18th to about the middle of the 19th century.

Although references and inventory records attest to the popularity of quilted articles, few surviving pieces predate the 17th century. One of the earliest is the Sicilian quilt, dating from about 1400, with scenes portraying the early life of Tristan. Part of this quilt is in the Victoria and

Albert Museum, London, and part in the Bargello at Florence. It is made of linen and quilted with linen thread, using both the back stitch and the darning stitch. The age, the fine craftsmanship of the stitching, the design, and the detail of the figures make this an excellent example of the quilting art.

By the 17th century quilting in Europe and in England began to reach a high degree of popularity that was to last about two centuries. Three fine examples from this period are preserved in the Victoria and Albert Museum. The first is a cotton bedcover quilted in Portugal, measuring 8 × 5 ft. 11 in., with a well-executed design of alternating single and double bird motifs. The other pieces are costume items of white satin stitched with white silk, the one a jacket and the other a doublet. Many examples of fine 18th-century English and European quilting remain as evidence of its wide and continued use.

In America the technique of quilting moved west with the early settlers. The most popular items were petticoats and quilts. Those produced in the early 18th century imitated English and Dutch designs, but by the end of the century the American quilt took on many new and distinctive features. First from necessity and later from choice, quilt tops were made of coloured fabrics appliquéd to a white muslin ground or joined together as patchwork; in some instances the two techniques were combined in one quilt. The design was completed by the quilting itself, which often picked up and echoed the shape of the patchwork or appliquéd pattern. Although a few examples can be found in other countries, this style is of American origin and was used more extensively there than elsewhere.

A popular late-18th-century design was the appliquéd tree of life, adapted from the painted cotton bedcovers then being imported from India. As styles changed, the tree of life was gradually decreased until it became merely a centre motif enclosed by frames of pieced chintz. From this the frames evolved as the more important design feature and the framed medallion became a second important pattern. Single-unit designs remained in vogue throughout the 18th century. Sometimes these were made of hundreds of small pieces stitched together—an effective way of

utilizing every available scrap of fabric. As the patchwork and appliqué became more dominant, the quilting frequently reverted to its original utilitarian purpose of holding the stuffing in position.

By the 19th century the quilt designs evolved into multiple units or repeated designs, either pieced or appliquéd. The patterns were of infinite variety and many were traditional. Another favourite was the one-patch, in which the entire quilt was made up of pieces cut in the same size and shape, the diamond and the hexagon being the two favourites.

The work of quilting a large bedcover, which might measure as much as 10 ft. square, was usually done on a frame, which could be as simple as two smooth poles or long bars of wood set on four chairs. Each sidebar of the quilting frame was covered with fabric to which the edges of the quilt lining were sewn, one side to each bar. The cotton or wool fibres used for the stuffing or filling were spread smoothly and evenly on the stretched lining. Then the top was placed in position and its edge was pinned or basted to the edge of the lining, drawing it tightly over the fibre filling. The quilting pattern was marked on the top with a tracing wheel and chalk, by pencil, or by pressure of the needle marking an indentation around a rigid pattern of wood. The running stitch was most commonly used for the quilting, but even this simple stitch was difficult through three layers of textile. Some of the fine 19th-century quilts have heavily stuffed or padded areas that enhance and emphasize the design. In these, the quilts were first stitched in the normal manner. Then the quilts were turned wrong side up, small holes were made in the lining, and considerably more fibre was forced into the desired area. A heavily padded effect took much painstaking work but produced beautiful "stuffed work" quilts.

The invention of the sewing machine in the mid-19th century was quickly followed by a series of attachments for machine-stitched quilting. Utilitarian items were quilted in this manner, but stitching by machine did not lend itself to artistic work. The creative impulse in quilt design also diminished. Although fine quilts were made after the mid-19th century, they usually copied or adapted earlier styles.

QUIMBY, PHINEAS PARKHURST (1802–1866), U.S. pioneer in the field of mental healing and generally regarded as the father of the New Thought movement, was born in Lebanon, N.H., on Feb. 16, 1802. His active career was spent largely in Belfast and Portland, Me., and he died at Belfast on Jan. 16, 1866.

Professionally interested in hypnosis (*q.v.*), Quimby employed it for a time as a means of healing, but later discovered that he was quite as able to heal by suggestion. He came to believe that illness resulted from the patient's mistaken beliefs, and that its cure lay in discovering the truth. Not primarily religious in the orthodox sense, he believed that he had rediscovered the secret of Jesus' healing ministry. He wrote down his philosophy in the so-called Quimby manuscripts. Quimby became a controversial figure because Mary Baker Eddy (*q.v.*), who sought healing at his hands, and was at first a disciple and warm admirer, later denied, as it was thought by many, that she had been influenced by him. It is the official belief that her discovery of Christian Science (*q.v.*), a divine revelation, depended in no sense on Quimby.

The best source is *The Quimby Manuscripts*, edited by H. W. Dresser (1921), the first edition of which contains a number of letters of Mrs. Eddy to Quimby and others not found in later editions. See also *NEW THOUGHT*. (C. S. B.)

QUIMPER (from the Breton *kemper*, a "confluence"), the chief town of Finistère département, Brittany, France, and the seat of a bishopric, stands at the confluence of the Odet and Stéir rivers, 127 mi. (205 km.) W of Rennes by road. Pop. (1962) 40,223. Most of the town is on the right bank of the Odet, lying among seven hills. On the left bank of the Odet are the wooded

slopes of Frugy Hill below which is the site of the Roman Locmaria, with a Romanesque church, partly of the 11th century. The cathedral of Saint-Corentin, in the heart of Quimper, is a fine Gothic building of the 13th–16th centuries. There are two museums. An annual festival is held in July at which all the costumes of Brittany are displayed.

Quimper is linked by rail and road with Brest, Nantes, and Rennes, and has an airport (4½ mi. [7 km.]) with internal and external air services. It is the tourist centre for south Brittany. The traditional craft of faïence has long been carried on at Quimper, and there are large potteries on the left bank. There are also some metal and other industries.

After Roman times Quimper became the capital of the *comté* (county) of Cornouaille (Cornwall, the name brought from Britain), and the first bishop, at the end of the 5th century, was St. Corentin. The *comté* was united with the duchy of Brittany in the 11th century, but the town suffered in the local wars of succession and in 1344 was sacked by Charles of Blois. The duchy returned to the Montforts (John V), however, after the defeat of Charles at Auray in 1364.

Notable people born at Quimper include Élie Catherine Fréron (1718–76), the polemical writer and opponent of Voltaire; Yves Joseph de Kerguelen-Trémarec (1734–97), the navigator whose discoveries included the Kerguelen Islands in the southern seas; and René Théophile Hyacinthe Laënnec (1781–1826), the inventor of the stethoscope. (Se. C.)

QUIN, JAMES (1693–1766), a leading English actor of his day, was born in London on Feb. 24, 1693. He made his first stage appearance at the Smock Alley theatre, Dublin, as Abel in Sir Robert Howard's *The Committee* in 1712. Engaged at Drury Lane theatre for small parts, his remarkable memory enabled him to deputize at short notice as Bajazet in *Tamerlane* with great success. Quin then went to Lincoln's Inn theatre and remained there for 14 years. A noted swordsman, he was convicted of manslaughter for killing another actor in a duel, and at Lincoln's Inn he defended the stage with his sword against rioters. He went to Covent Garden theatre in 1732 and became a leader of the stage, returning to Drury Lane from 1734 to 1741. His style was declamatory, very slow but impressive, and he always wore the same costume. In 1746 his supremacy was challenged by David Garrick (*q.v.*), the exponent of a new type of acting, and when the two played together in *The Fair Penitent* at Covent Garden, Garrick triumphed. Quin bore him no ill will; they became friends and acted together at Drury Lane. Quin was one of the finest Falstaffs the stage ever knew. He retired to Bath in 1757 and died there on Jan. 21, 1766, being buried in the abbey church with an epitaph by Garrick. Although of poor education, Quin had great wit and warmhearted generosity. He was also a great epicure, his appetite being as prodigious as his memory.

See *Life of Mr. James Quin, Comedian*, anon., 2nd ed. (1887). (W. J. M.-P.)

QUINAULT, PHILIPPE (1635–1688), French dramatist and one of the collaborators with Lully in the creation of French opera, was born in Paris on June 3, 1635. By 1666 he had written 16 comedies, tragedies, and tragicomedies. He later wrote librettos for Lully, creating with him the form of the *tragédie-lyrique* which became the model for French opera. Their first work in this form was *Cadmus* (1673), followed, between 1674 and 1683, by *Thésée*, *Atys*, *Isis*, *Proserpine*, *Persée*, and *Phaëton*. He was particularly successful in his later romantic works, *Amadis* (1684), *Roland* (1685), and *Armide* (1686). His librettos long survived him and were used, with variations, by Gluck, Piccini, and Gossec. Though his reputation later suffered by comparison with Racine, his plays were popular, providing a theatrical counterpart of the polite novel, and presenting an ideal world less heroic than that of Corneille and less harrowing than that of Racine. He died in Paris on Nov. 26, 1688.

QUINCE, a fruit tree classified by some botanists as a distinct genus, *Cydonia*, and by others as a section of the genus *Pyrus* (family Rosaceae, *q.v.*).

The name *Cydonia oblonga* is to be preferred to *Pyrus cydonia*. Bailey gives five varieties of *C. oblonga*, namely, varieties *lusitanica*, *maliformis*, *pyriformis*, *marmorata* and *pyramidalis*. The quinces are much-branched shrubs or small trees with entire leaves, small stipules, large solitary white or pink flowers like those of the pear or apple, but with leafy calyx lobes and a many-celled ovary, in each cell of which are numerous horizontal ovules. The fruits may be round and flattened or somewhat pear-shaped, with large leafy calyx persisting on the mature fruit.

The common quince is a native of Iran and Anatolia, and perhaps also of Greece and the Crimea. By Franchet and Savatier *C. oblonga* is given as a native of Japan, with the native name "maroumerou." It is certain that the Greeks knew a common variety upon which they grafted scions of a better variety from Cydon in Crete, whence it was obtained and from which the later names have been derived. The fragrance and astringency of the fruit of the quince are well known, and the seeds formerly were used medicinally for the sake of the mucilage they yield when soaked in water. The quince is but little cultivated in Great Britain; in Scotland it seldom approaches maturity, unless favoured by a wall. The fruit has a strong aroma and in the raw state is astringent; but it makes an excellent preserve, and is often used to give flavour and sharpness to stewed or baked apples.

The Japanese quince, formerly considered in the genus *Cydonia* but now known as *Chaenomeles lagenaria*, has been widely used as an ornamental plant in gardens as a shrub, particularly because of the beauty of its flowers that appear on the stems before the leaves open fully in late winter and early spring months. Some of the small shrubs bear large green fragrant fruits that are quite inedible in the fresh state but have been used in making preserves.

The quince was formerly grown in home fruit gardens and commercial plantings in the northeastern United States but later became the least esteemed of all tree fruits for orchards in that area. The fruit is almost inedible in the uncooked state, and other fruits are preferred in the fresh state for the diet. It thrives under the same systems of cultivation as do apples and pears and does fairly well along fence rows, where it may be given little care. The quince is susceptible to a bacterial disease called fire blight, which is also a serious hazard to pear growing in the United States. Trees that are not forced into strong vegetative growth by pruning and fertilization are less susceptible to the fire blight disease. The trees are subject to the same scale insects that attack apples and pears and should receive the same dormant spray treatment for the control of these pests. The fruits are golden yellow in colour and the flesh takes on a pink colour when cooked, giving an attractive colour to jellies and preserves made from this fruit. Orange and Champion are the more commonly grown varieties. Quince stocks are used on which to graft the pear to dwarf the tree and hasten early bearing. The Angers variety, imported from France, is the most important stock used for dwarfing pears.

QUINCY, a city of Illinois, U.S., on the Mississippi river, 110 mi. N.W. of St. Louis. First settled in 1822, it became the seat of Adams county, March 4, 1825, the day Pres. John Quincy Adams was inaugurated, and was named in his honour. Incorporated

as a village in 1834 and chartered as a city in 1839, Quincy had a population of about 7,000 and was second in size to Chicago when the sixth Lincoln-Douglas debate was held there in John's square (now Washington park), Oct. 13, 1858. A prosperous river town, Quincy declined with the passing of the steamboat era in the latter part of the 19th century but after 1920, with the development of industry, population again increased. Among the manufactures are agricultural and industrial machinery, automotive parts, clothing and footwear, food products, chemicals, office supplies, paper products and heating equipment.

Most of the city occupies the upland about 150 ft. above the valley floor where the Mississippi river flows against its steep left bank. A navigational dam and lock impound the water in Quincy bay. Riverview, Sunset and Gardner parks north of the business section and Indian Mounds and South parks to the south line the river bluffs. Quincy, a Roman Catholic coeducational college established in 1860, is in the residential part of the city. Illinois Soldiers and Sailors home (founded 1887) occupies more than 200 ac. at the northern city limits. For comparative population figures see table in ILLINOIS: *Population*.

(J. H. Gd.)

QUINCY, a city of Norfolk county, Mass., U.S., located on Boston harbour, about 8 mi. S.E. of Boston (*q.v.*). A part of the Boston standard metropolitan statistical area, it is a manufacturing city and a centre of retail trade. Pop. (1960) 87,409. (For comparative figures see table in MASSACHUSETTS: *Population*.) Manufacturing is diversified (gears, confections, dairy products, detergents, electronic tubes and machinery for riveting, packaging and materials handling) but it is dominated by shipbuilding. The Fore River shipyards are among the most important in the country. The city was formerly famed for its granite quarries, which supplied granite for King's chapel and the Bunker Hill monument in Boston. Retail sales per capita are substantially above the average for the Boston metropolitan area and for the state, with sales of lumber, building materials, hardware and farm equipment constituting nearly 10% of the total. Quincy's residents are distinguished by the high proportion with origins in Scotland, Sweden and Finland and by the predominance of craftsmen, foremen and clerical workers in the labour force. Prior to 1792, when Quincy was incorporated as a town, the area was part of the town of Braintree. It became a city in 1888. The birthplaces of two presidents, John Adams and John Quincy Adams, are preserved in Quincy. The two buildings, the Quincy homestead (built about 1636) and the Adams National Historic site, are open to visitors except in the winter season.

(E. E. M.)

QUINET, EDGAR (1803-1875), French patriot, poet, and philosopher, made a significant contribution to the developing tradition of French liberalism. He was born at Bourg-en-Bresse, Ain, on Feb. 17, 1803. Moving to Paris in 1820, he forsook the faith of his Protestant mother, became greatly attracted to German philosophy, and published in 1827-28, as his first major work, a translation of Herder's *Ideen zur Philosophie der Geschichte der Menschheit*. Soon, however, despite lengthy visits to Germany, he became disillusioned with German philosophy and alarmed by the aggressive nature of Prussian nationalism. His literary reputation was increased by the publication of his epic prose poem *Ahasvérus* (1833). In *Le Génie des religions* (1842) he expressed sympathy for all religions while committing himself to none, but shortly afterward his increasingly radical views alienated him finally from Catholicism.

It was not until 1842 that he obtained what he had really wanted—a professorship in Paris. There he joined his friends Jules Michelet and Adam Mickiewicz (*qq.v.*) at the Collège de France. His lectures attacked Catholicism, exalted the French Revolution, offered support for the oppressed nationalities of Europe, and promoted the theory that religions were the determining force in society. Because his treatment of these topics aroused heated controversy, the government intervened in 1846 and, to the satisfaction of the clergy and dismay of the students, he lost his chair.

Quinet hailed the revolution of February 1848, but, with Louis Napoleon's *coup d'état* of December 1851, was forced to flee first to Brussels (1851-58), and thence to Veytaux, near Montreux, Switzerland (1858-70). His faith in humanity shaken, Quinet's

ROCHE
QUINCE (*CYDONIA OBLONGA*) BLOSSOMS

optimism failed him for a while, and in *La Révolution religieuse au XIX^e siècle* (1857) and *La Révolution* (1865), he sympathized with the use of force against an all-powerful church, and even wistfully hoped that France might yet embrace Protestantism. In his last years the conquests of science fascinated him and restored his faith in the progress of humanity (*La Création*, 1870; *L'Esprit nouveau*, 1874). He returned to Paris on the fall of the Empire in 1870, and was elected to the National Assembly in the following year, but exercised little influence over his fellow deputies. He died at Versailles on March 27, 1875.

Although Quinet was never insensitive to popular acclaim, he lived mainly in the world of ideas. His interests ranged widely, and frequently he allowed his imagination to outstrip his sense of academic caution. His histories, political essays, and works on the history of religion, though little read today, remain full of suggestive theories. His style inclined to the vague and the abstract, for which he has wrongly been credited with mystical tendencies. It is in the educational reforms of the Third Republic, including the banishing of religious instruction from the schools, that his most lasting influence is seen. Yet, because the schools failed to provide their own moral instruction, the results were far from what Quinet would have wished.

QUININE is the most important alkaloid of cinchona bark; its chief use is in the treatment of malaria. In the 300 years between its introduction into western medicine and World War I, quinine was the only effective remedy for malaria. As a specific for this disease, quinine benefited more people than any drug ever used for the treatment of infectious diseases. The treatment of malaria with quinine marked the first successful use of a chemical compound in combating an infectious disease.

Like the other cinchona alkaloids, quinine is a large and complex molecule, and its total laboratory synthesis by Robert B. Woodward and William von E. Doering in 1945 is one of the classical achievements of synthetic organic chemistry. However, commercial synthesis of quinine is not economically feasible.

Cinchonine, $C_{19}H_{22}N_2O$, the desmethoxy derivative of quinine, is one-fifth as active as quinine.

Quinine acts by interfering with the growth and reproduction of the malarial parasites inhabiting the red cells of the blood, probably by preventing them from oxidizing glucose, their chief source of energy. Administration of quinine dramatically improves the condition of a person suffering from malaria; the parasites promptly disappear from the blood, and the symptoms of the disease are quickly alleviated. However, when quinine treatment is terminated, many recovered patients suffer another attack of malaria several weeks later. This is because quinine does not kill the malarial parasites living in cells of the body other than the red blood cells. These parasites persist and, after a time, reinvade the red blood cells and precipitate the second malarial attack, or relapse.

Because quinine fails to produce a complete cure in malaria, better antimalarial drugs were long sought for. At the beginning of World War II, two new synthetic antimalarial drugs, pamaquine naphthoate (Plasmochin) and quinacrine hydrochloride (Atabrine), had already been developed in Germany. They were defi-

nately effective but not clearly superior to quinine. When the Allies' supply of East Indian quinine was cut off by the entrance of Japan into World War II, the search for new and more effective antimalarial drugs was greatly intensified. Although Atabrine remained the mainstay of Allied forces throughout the war, wartime research produced a number of antimalarial drugs that later almost completely replaced quinine. Some of them, such as chloroquine and chlorguanide, are more effective than quinine in suppressing the growth of the blood forms of the malaria parasite; while others, such as primaquine and pyrimethamine, act upon both the blood and tissue stages of the parasite, thus producing complete cures and preventing relapses. All the newer antimalarials, unlike quinine, may be completely synthesized in the chemical laboratory on a commercial scale.

During the 1960s several strains of the malaria parasite *Plasmodium falciparum* developed resistance to the synthetic drugs, particularly the highly valued chloroquine. The parasite remained sensitive, however, to quinine, which had to be reinstated in various parts of the world as the drug of choice in spite of the side effects (see below) which sometimes occur when the necessarily massive doses of quinine are given.

In addition to its specific use in malaria, quinine is sometimes used as a nonspecific remedy for fever and pain. It probably reduces fever by dilating the small vessels of the skin, while its analgesic effect may result from depression of certain centres in the central nervous system. Prolonged administration of quinine may produce toxic symptoms such as deafness, disturbances in vision, skin rashes, and digestive upsets; and, in the opinion of some experts, patients who undergo quinine treatment may be predisposed to develop blackwater fever, a little-understood complication of malaria marked by rapid and severe anemia and the appearance of hemoglobin in the urine.

See also CINCHONA; CINCHONA BARK, ALKALOIDS OF; MALARIA; and references under "Quinine" in the Index. (J. W. MR.; X.)

QUINOLINE is an organic compound of formula C_9H_7N which in general chemical behaviour resembles pyridine (q.v.) very closely. It is, in fact, a benzopyridine, bearing the same relation to pyridine as naphthalene does to benzene. The benzene and pyridine rings are fused together in the 2,3 position, the other possibility, fusion in the 3,4 position, giving isoquinoline which is discussed below.

The positions of substituents in derivatives of the two compounds are indicated by numbers as shown above. The prefixes α , β and γ were also used formerly for the pyridine ring of quinoline.

Quinoline itself was first isolated from coal tar by F. F. Runge in 1834. The modern commercial product is obtained from that source or is made synthetically. It also occurs in bone oil. C. F. Gerhardt in 1842 obtained quinoline by heating the alkaloid cinchonine with potassium hydroxide and this was the first evidence of the occurrence of the quinoline nucleus in certain of the natural alkaloids; quinine similarly heated gives 6-methoxyquinoline.

The first synthesis of quinoline was achieved by W. Koenigs in 1879 by passing the vapour of allylaniline over hot lead oxide. A large number of further synthetical methods are available for the preparation of quinoline and its derivatives. Of these, the best known is probably the Skraup reaction (1880), which is of exceedingly wide application; it is employed for the formation of quinoline itself and for that of the derivatives substituted in the benzene ring. A primary aromatic amine is heated with glycerol, sulfuric acid and a mild oxidizing agent, nitrobenzene or arsenic acid being often used. Aniline is converted into quinoline in good yield by this method which can also be applied to practically all aromatic amines.

As was mentioned above, the natural alkaloid quinine contains

the quinoline nucleus. Several synthetic antimalarial drugs, which are like quinine in being derivatives of 4-aminoquinoline, have also been prepared; of these, quinacrine (Atabrine) has found the widest use. (See MALARIA.)

Quinoline is a colourless, highly refractive oil boiling at 239° C. and with a characteristic smell. It is almost insoluble in water but miscible with organic solvents, and it behaves as a weak monoacidic base. Its salts are readily soluble in water except the bichromate which is sparingly soluble in the cold and can be used for the purification of quinoline. Since the pyridine ring is deactivated by the presence of the nitrogen atom, a substituting reagent such as nitric acid attacks the benzene ring and gives a mixture of the 5- and 8-substituted compounds. Further nitration gives the 5,7- and 6,8-dinitro derivatives.

These nitro compounds can be reduced to amines which behave as true aromatic amines and can be diazotized and converted into other derivatives. Anionoid substituting reagents, such as sodamide, react with the pyridine nucleus in the 2 and 4 positions, and 2-aminoquinoline can be obtained directly by the action of sodamide.

Quinoline and its homologues are tertiary bases and thus react with alkyl halides to give quaternary ammonium salts which show the normal behaviour of strong electrolytes. The quaternary hydroxides derived from these salts are not stable and tend to pass more or less completely into un-ionized forms, as with many other cyclic bases. The reactivity of these compounds is the basis for the preparation of dyestuffs of the cyanine class (isocyanines, pseudocyanines and carbocyanines) which are of great value as sensitizers of the photographic emulsion to wavelengths in the red and infrared.

Isoquinoline is found in coal tar and crude quinoline from that source contains about 4% of isoquinoline. It is a solid melting at 24° C. and boiling at 240° C. and with a smell quite different from that of quinoline. It is more strongly basic than the latter, since the nitrogen atom is not directly attached to the benzene ring, and its sulfate is not very soluble in cold water; separation from quinoline is based on these facts.

The isoquinoline nucleus is found in a number of important alkaloids; e.g., papaverine, berberine, hydrastine and narcotine. A valuable reaction for synthesizing this nucleus is that of A. Bischler and B. Napieralski (1893). Acyl derivatives of β -phenylethylamines when heated with powerful dehydrating agents in boiling xylene or tetralin give 3,4-dihydroisoquinolines which can be dehydrogenated to isoquinolines with permanganate or catalytically with palladium. Many of the isoquinoline alkaloids have been synthesized by means of this reaction. (T. W. J. T.)

QUINONES, a group of coloured cyclic organic compounds containing two carbonyl groups, C = O (see ALDEHYDES AND KETONES), either adjacent (orthoquinone, I) or separated by a vinyl group, C = C, (paraquinone, II) in a usually six-membered unsaturated ring. All quinones have these features except a few in which the carbonyl groups are located in different rings: e.g., anthraquinone, III. The term quinone usually refers to the specific compound parabenzoquinone (*p*-benzoquinone), II, but it may also apply to any other compound having the required structural features.

A similar ambiguity exists also for the terms hydroquinone and quinhydrone (see below). The general reactions of quinones are entirely analogous to the specific reactions of *p*-benzoquinone.

By a variety of reducing agents, *p*-benzoquinone is easily and quantitatively reduced to its corresponding hydroquinone, IV. This change is readily reversed by oxidizing agents:

Photographic development is largely a reflection of this oxidation process. Most general-purpose developers are a mixture of hydroquinone and Metol, Elon, or a similar *p*-aminophenol derivative. Contact of the silver salt in the photographic emulsion with the hydroquinone causes reduction of the salt to metallic silver, while the dissolved hydroquinone is oxidized to quinone. This reaction tends to be very sluggish at temperatures below 50° F (10° C),

III

IV

so that for ordinary purposes warmer solutions must be used.

If a platinum electrode is put into a solution which contains equivalent amounts of some quinone and its hydroquinone, and which is saturated with respect to the addition compound of the two (the so-called quinhydrone), an electric potential is produced which is dependent on the hydrogen ion concentration. By making connection through a suitable conducting solution with a reference half cell, this potential can be measured. A device called the quinhydrone electrode was developed to make use of the above principle in measuring the hydrogen ion concentration of an unknown solution.

The ring of atoms in a quinone is said still to have a quinonoid (or quinoid) character if one of the sets of doubly bonded carbon and oxygen atoms is replaced by another doubly bonded atom pair, or even if both of those sets are so replaced. Quinonoid structures are important in theories concerning the relationship of chemical constitution to colour. Many quinones, among which one of the most important is anthraquinone (see ANTHRAQUINONE), are used as dyestuff intermediates. All vat dyes have quinonoid structures. An important feature in the use of vat dyes is the fact that the dye is placed on the cloth while in the hydroquinone state, and the oxidation to the quinone state takes place on exposure to air. (See DYES AND DYEING.)

Many quinones occur in natural products. One of the most important of these is vitamin K₁, which possesses the structure V and is the antihemorrhagic agent found in certain green plants. (See VITAMINS: Vitamin K.) Synthetic quinones, in particular 2-methyl-1,4-naphthoquinone, VI, have similar properties and are used in medical practice.

V

VI

A number of interesting naturally occurring quinones are described in *Advanced Organic Chemistry* by L. F. Fieser and M. A. P. Fieser, pp. 845-875 (1961). (M. S. N.; X.)

QUINTANA, MANUEL JOSÉ (1772-1857), Spanish patriot and poet, was born in Madrid, April 11, 1772. A typical Spanish neoclassic, he wrote tragedies (*El Pelayo*), eloquent organ-voiced odes on large humanitarian themes, dared comparison with Plutarch—*Vidas de españoles célebres* (1807-33)—and wrote the best literary criticism of the century in his anthologies *Colección de poesías castellanas* and *Musa épica*. The national respect he earned for his clarion calls for unity against the French invaders never waned (Queen Isabel crowned him national poet in

1855), though his liberalism excluded romanticism and his pen was silent for half a century before his death in Madrid, March 11, 1857. (R. F. B.)

QUINTANA ROO, a federal territory of Mexico on the eastern side of the Yucatán peninsula, bounded by British Honduras and Guatemala. Pop. (1950) 26,967; (1960) 50,169; area, 16,228 sq.mi. (42,031 sq.km.); formed in 1902 from parts of the states of Yucatán and Campeche. The territory is hot, humid, and heavily forested, with 50 to 60 in. (127 to 152 cm.) of rain annually. Like the rest of the peninsula, Quintana Roo is a level, porous limestone plain through which water percolates to form underground grottoes, caverns, and wells.

The area is populated chiefly by descendants of Maya Indians who in 1847 rebelled in Yucatán and were eventually driven into these fastnesses by continuous military campaigns. Distrustful of Yucatecan Mexicans, they carry on sporadic trade in chicle with British Honduras. Their main contacts with the outside world lie along the narrow-gauge railway that connects Felipe Carrillo Puerto (Santa Cruz de Bravo) to Vigía Chico on Ascensión Bay. Another penetration from the coast inland is by a rail line in the northern section from Leona Vicario (Santa María) to Puerto Morelos. Air strips at various points, and regular service to Belize, British Honduras, and Mérida lessened some of the characteristic isolation of the territory, which for many years was used as a dumping ground for political prisoners.

Chicle and a small amount of copra, produced on the coast near Cozumel Island, are the main products. There are valuable stands of mahogany and other hardwoods which are largely unexploited. Sponge and turtle fishing is significant along the coast. The small Mayan hamlets are nearly self-sufficient.

The capital is Chetumal. The territory contains numerous important archaeological remains of the earlier pre-Spanish Mayan Empire, notably those at Tulum.

In 1517 the first Spanish landing in Mexico was made at Cape Catoche. Hernán Cortés in 1519 landed first on the island of Cozumel alongside Quintana Roo. An airline links the island, now a tourist resort, with Mérida. (J. A. Cw.)

QUINTESENCE, according to some Renaissance philosophers (Paracelsus, Heinrich Cornelius Agrippa, Rudolf Goelen), was the purest and most intimate nature of created things. Earlier the Latin term *quinta essentia*, "fifth essence" (equivalent to the Greek *pempte ousia*, which occurs in John Philoponus), was used to denote the thinnest and most divine material element surrounding the world of the four Empedoclean elements (fire, air, water, and earth); the Pythagorean Philolaus (*q.v.*) spoke of a *pempton soma* or "fifth body"; and Aristotle described the ether as a primary substance distinct from the other four. (L. M.-Po.)

QUINTILIAN (MARCUS FABIVS QUINTILLANUS) (c. A.D. 35-c. 100), Roman writer whose work on rhetoric is one of the most valuable contributions of the ancient world to educational theory and to literary criticism, was born at Calagurris in Spain (the modern Calahorra in the Logroño province). He received at least part of his education in Rome; the orator Domitius Afer had a share in his training. He went back to Spain (not before A.D. 57), then returned to Rome in the retinue of Galba (68). There he taught rhetoric and was subsequently (c. 71?) appointed a public professor of that subject by Vespasian. The younger Pliny was among his pupils. At the same time he was a successful pleader in the law courts. After 20 years spent in these activities he retired (c. 90) and devoted himself to writing; it took two years to compose his great work, the *Institutio oratoria* ("The Training of an Orator"), which was published c. 95. He achieved fame and wealth; ultimately Domitian made him tutor of his two grandnephews, prospective heirs to the throne, and awarded him the consular insignia. The preface to book vi of the *Institutio* expresses in tenderest terms his grief for the loss of his young wife (when she was 19) and of both his very young sons.

The *Institutio oratoria* was written at a time when, political life being no longer free, eloquence had lost its former power. But it had not lost its prestige. Rhetoric dominated education—in the form essentially of a training in liberal culture. The *Institutio*, in 12 books, provides a comprehensive course of in-

struction taking the student from infancy to the time when he has become a complete orator. Book i deals with the training prior to the study of rhetoric, book ii with the first rhetorical exercises and with declamation, and also with the nature and end of oratory. These two books contain the best Roman thought on education, much of it of enduring value for its practical good sense, sympathetic personal quality and insight into human nature. "Grammar" is considered in its two departments, the art of speaking correctly and the interpretation of literature. Books iii–xi are concerned with the five departments of rhetoric: books iii–vi with "invention" (iii discusses also the origin of rhetoric, and its kinds—of these the judicial receives most attention in the *Institutio* as a whole; in iv–vi invention is applied to the formal parts of a discourse; and vi includes a lively chapter on the arousing of laughter); book vii with arrangement; books viii–x with style (in viii and ix the elements of a good style are treated, and in x various practical methods of assuring command over them).

Book x contains the much-praised survey of Greek and Latin authors recommended to the orator for study, with neat summaries of their outstanding qualities. Often Quintilian gives us the established opinions of his time, but sometimes again he is independent, especially with respect to Roman writers; and his exposition is felicitous and interesting. He reproves certain stylistic abuses of his day (and the influence of Seneca) and would effect a return to the classical tradition of the Golden Age (his greatest admiration is for Cicero), but with concessions to the demands of changed conditions. The subjects of book xi are memory and delivery.

Quintilian's aim was to mold the character as well as to train the intellect (iv, preface, 3); and book xii delineates the ideal orator—taking the elder Cato's definition, "a good man skilled in speaking"—and offers advice for the employment of his gifts in public life. Since eloquence serves the public welfare, it must be fused with virtue; and philosophy is a component part of the rhetorical training. The moral power of this book makes it especially impressive and induces one to overlook the author's occasional lapses, as when he asserts with worldly wisdom that "Sometimes the public interest requires that the speaker defend what is not true" (ii, 17, 36) or accords fulsome praise to Domitian (iv, preface, 3–5).

Quintilian reviews and studies the principles of rhetoric in their fullest scope and variety, preserving what is valuable in the Greek and Roman tradition, but without slavish adherence to any one school; he applies discriminating judgment where the doctrines of his predecessors are contradictory, rejects them when they are absurd. He scorns superstitious conformity to rules as though they were immutable laws and particularly to such as are laid down without experience of actual battle in the courts. The work is everywhere marked by learning, wisdom and taste; and the engaging personality of the author, combining kindness, sincerity and high principle, shines through it.

Quintilian's style exhibits some of the characteristics of the silver Latin, such as point, the use of rare and poetic words, and occasional looseness of structure, but no writer of his time departs less widely from the best models of the late republican period. The language is on the whole clear, unlaboured, energetic and dignified.

The *Institutio* exerted its greatest influence during the Renaissance and Reformation, after the discovery of a complete text by Poggio at St. Gall (Sankt Gallen) in 1416.

For the text of the *Institutio oratoria* see the edition by L. Radermacher, 2 vol. (1907–35); for the text with Eng. trans., that by H. E. Butler in the "Loeb Series," 4 vol. (1921–22). For commentary see Jean Cousin, *Études sur Quintilien* (1936), and the separate editions of book i by F. H. Colson (1924), of book x by W. Peterson (1891; new ed., 1903) and of book xii by R. G. Austin (1948). The text of *Declamationes maiores* is ed. by G. Lehnert (1905), that of *Declamationes minores* by C. Ritter (1884).

Quintilian published one other rhetorical work, *De causis corruptae eloquentiae*, which has not survived: it probably dealt with the technical and educational aspects of the decline of

oratory rather than the political and social. Of his speeches he published only one (now also lost), in defense of Naevius Arpinianus, accused of killing his wife. The other speeches that once circulated under his name he repudiated as having been corrupted by careless stenographers bent on profit (vii, 2, 24). He disowned also two books on rhetoric which kindly intentioned pupils had published from lecture notes without his authorization (i, preface, 7). Neither of the two extant collections of declamations ascribed to him (*Declamationes maiores*, 19 in number; and *Declamationes minores*, 145 from a collection originally numbering 388) is regarded as genuine; both are of uncertain date.

(HY. CN.)

QUINTILLUS (MARCUS AURELIUS CLAUDIUS QUINTILLUS), Roman emperor A.D. 270, was the brother of the emperor Claudius Gothicus, on whose death he was proclaimed emperor at Aquileia. He died or was killed a few weeks later.

(JN. R. M.)

QUINTUS SMYRNAEUS (fl. c. A.D. 375), Greek epic poet, author of a hexameter poem in 14 books, narrating events at Troy from the funeral of Hector to the departure of the Achaeans after sacking the city (and hence called *Ta met' Homerom* or *Posthomerica*). Quintus claims that the Muses inspired him when, still a beardless lad, he kept sheep near the temple of Artemis (xii, 308–313). His style is monotonous, and his vocabulary and metrics are alike traditional, but his very unoriginality makes his work a valuable guide to the content of the lost epics (*Aethiopis*, *Little Iliad*, *Iliupersis*) which had provided men of the classical period with their information about the last days of Troy.

BIBLIOGRAPHY.—Edition with English verse trans. by A. S. Way in the Loeb series (1913, reprinted 1943). See also F. Vian, *Recherches sur les Posthomerica de Quintus de Smyrne* (1959). For Quintus' relations with earlier epic see W. Kullmann, *Die Quellen der Ilias* (1960), and R. Heinze, *Virgils epische Technik*, 3rd ed. (1915, reprinted 1957). C. A. Sainte-Beuve, *Étude sur . . . Quinte de Smyrne*, 3rd ed. (1878), is still worth reading.

(JN. A. D.)

QUIPU, a knotted cord used by the Incas of ancient Peru and other Indians of the central Andes as a mnemonic aid and recording device. Many quipus were found in Inca graves and have been acquired by museums. They were still (1960s) in limited use as simple recording devices in the central Andes. The Inca type consisted of a heavy, central cord from which 1 to 100 variously coloured strings were suspended. A single knot or loop in a pendant string represented a number from 1 to 9, depending on the distance of the loop from the central cord. There also were positions for tens, hundreds, thousands, and ten thousands. Various meanings have been suggested for the different colours used, such as: white for silver, yellow for gold, black for elapsed time (nights), red for soldiers or warfare. Different types of knots were employed, lumped together or spaced in certain ways.

Quipus were used to record statistical information, such as census reports, numbers of livestock, and production figures; probably they were used also in recording and reciting genealogies, in narrating legends, and for recalling the proper order of complex ceremonial events. As time went on, historical events, laws, and edicts may have been communicated by means of quipus. Apparently the quipu was not a calculating device, since the Incas seem to have used a pebble-type abacus for that purpose. In the Guianas, knotted strings were used as timekeepers for ceremonial events; and similar mnemonic devices were used in the Old World. See also MESSAGE STICK.

See J. H. Steward (ed.), *Handbook of South American Indians*, vol. 5, pp. 616–619, with bibliography (1949); J. H. Steward and L. C. Faron, *Native Peoples of South America* (1959).

(L. C. FA.)

QUIRINO, ELPIDIO (1890–1956), second president of the Republic of the Philippines, was born Nov. 16, 1890, in Vigan, in Ilocos Sur Province, on the island of Luzon. He attended high school in Manila and took his law degree at the University of the Philippines. Quirino served in the Philippine House of Representatives (1919–25) and in the Senate (1925–31). He was a member of the Philippine independence mission which helped to obtain the passage in the U.S. Congress in 1934 of the Tydings-McDuffie Act under which the Philippines achieved independence on July 4, 1946. Also in 1934 he was elected to the Constitutional Convention. Thereafter he served as secretary of finance and later as

secretary of the interior in the Commonwealth government (1935–38). He was elected to the Senate in 1941 and stayed in the Philippines during the Japanese occupation. After the war, Quirino again became secretary of finance in May 1946. As the candidate of the newly formed Liberal Party, he became vice-president and secretary of foreign affairs of the new republic in July 1946. He succeeded to the presidency on the death of Pres. Manuel Roxas in 1948 and was elected president in 1949. During his term of office an intensive program of economic development was initiated with the assistance of the United States, the treaty of peace was signed with Japan, and a new mutual defense treaty was concluded with the United States in 1951. The Hukbalahaps, or social dissidents in Luzon, were pacified primarily because of the efforts of his secretary of defense, Ramón Magsaysay. After being defeated for reelection in 1953 by Magsaysay he retired to private life and died on Feb. 28, 1956.

Quirino's six years as president were marked by notable post-World War II reconstruction progress and by general economic gains, although members of his administration were accused of corruption in office—which contributed to his 1953 defeat despite his vigorous campaigning in the midst of serious illness. See also PHILIPPINES: History.

(C. A. B.)

QUIRINUS, a major Roman deity ranking close to Jupiter and Mars (*qq.v.*). Their *flamines* constituted the three major priests at Rome. His name is in adjectival form and would seem to mean “he of the *quirium*,” a word generally taken to signify the very ancient Sabine settlement which united with the Palatine community to form the original Rome. It has also been derived, however, from *covirium*, meaning “assembly of men.” That the Quirinal, traditional site of Sabine settlement, was the seat of his cult there is no doubt, and the Sabine origin of the god is reflected in Ovid (*Fasti* II, 475). In spite of his importance rather little is known about Quirinus. He bears a similarity to Mars, and some believe that he is only another form of that deity. By the late republic he is identified completely with Romulus, a confusion perhaps originally suggested by Quirites (*q.v.*). (See also ROMULUS AND REMUS.) He had a festival, the Quirinalia, on Feb. 17; his temple on the Quirinal was one of the oldest in Rome. A cult partner Hora is spoken of, also minor deities, the Virites Quirini, of whom nothing else is known. Janus (*q.v.*) appears with the epithet Quirinus, but the relationship between the two is a matter of conjecture.

BIBLIOGRAPHY.—W. W. Fowler, *Roman Festivals*, pp. 322–324 (1899); G. Wissowa, *Religion und Kultus*, 2nd ed., pp. 153 ff. (1912); F. Altheim, *History of Roman Religion*, pp. 138 ff. (1938).

(R. B. LD.)

QUIRITES, an early term, of uncertain derivation, for the citizens of Rome. Ancient scholars associated the word with Sabine *Cures* as typifying the Sabine element in Rome, with the Sabine deity Quirinus and the Quirina tribe. In the phrase “*populus Romanus Quiritium*” it denoted the individual citizen as contrasted with the community, and *ius Quiritium* in Roman law denoted the full body of rights of Roman citizenship. Any military connotations were soon lost, so the term refers to citizens as civilians. Julius Caesar, it is said, quelled a mutiny among his soldiers by addressing them as “Quirites.”

(T. R. S. B.)

QUIROGA, HORACIO (1878–1937), Uruguayan short-story writer, became famous for his ability to portray man's futile struggle against the tropical jungle in the Argentine territory of Misiones. Born Dec. 31, 1878, in Salto, he spent a good part of his life in Argentina, taking frequent trips from Buenos Aires to San Ignacio in the jungle province of Misiones. This primitive environment as well as his many personal experiences in the jungle furnished material for most of his *cuentos*.

His early period of literary apprenticeship, marked by his tendency to emulate the modernistic fashion, is reflected in his first book, *Los arrecifes de coral* (1901), a collection of prose and verse; he soon realized, however, that his talent was better suited to short stories. Some of his finest compositions, *Cuentos de la selva* (1918), *El salvaje* (1920), *Anaconda* (1921), *El desierto* (1924), *Los desterrados* (1926), and others, belong to this genre. *Más allá* (1935) reflects the depressed mood of his later years when he suf-

fered from ill health and other misfortunes.

Quiroga took his own life in a charity hospital in Buenos Aires, Feb. 19, 1937. (H. Co.)

QUISLING, VIDKUN ABRAHAM LAURITZ JONSSON (1887–1945), Norwegian fascist whose name became synonymous with "traitor." An army officer, he served as military attaché in Petrograd (later Leningrad) and Helsinki and later assisted Fridtjof Nansen in Russian relief. From 1927 to 1929 he represented British interests at the Norwegian legation in Moscow. He became Norwegian minister of defense in the Agrarian government, 1931–33. Resigning, he founded the fascist Nasjonal Samling (National Union) Party, but never won a seat in the *storting*. Friendly to the Nazis, he visited Hitler in December 1939 and collaborated in the German invasion of Norway in April 1940. The new regime proclaimed by him so incensed the Norwegians that it collapsed within a week, but he continued to lead Nasjonal Samling, the only party permitted by the Germans. On Feb. 1, 1942, Reichskommissar Joseph Terboven named him "minister president." Quisling's attempts to nazify the Norwegian Church, schools, and youth aroused bitter opposition. He persecuted the Jews, sending almost 1,000 to death in concentration camps. Despite difficulties with his party and the Germans, he held office until Norway was liberated in May 1945. Arrested, tried, and found guilty of treason and other crimes, he was executed on Oct. 24, 1945. (Ho. Ln.)

QUITO, the capital of Ecuador and of the province of Pichincha, is situated about 114 mi. (183 km.) from the Pacific in a narrow Andean valley. Pop. (1962) 354,746. It was already an ancient city when the Spaniards arrived there in the 16th century. Before them there were the Incas, to whose empire it had belonged since 1487. Between that date and the year 1000 it was ruled by the Shyris, sovereigns of the Caras who are said to have come "by way of the sea." Prior to the Caras, it was the seat of the kingdom of the Quitus, the largest unit of an Indian tribal confederation that left no recorded history. Sebastián de Belalcázar, one of Pizarro's lieutenants, occupied it on Dec. 5, 1534. In the presence of his soldiers and 206 native inhabitants, he set up a municipal council (*cabildo*) and declared it in operation. He planned Quito as a typical Spanish city with streets running north and south, east and west from the central square or *plaza mayor*.

Quito lies on the lower slopes of the Pichincha (15,700 ft. [4,785 m.]), a volcano that last erupted in 1666. The central plaza, bounded by the cathedral, the palaces of the president and the archbishop, and the municipal building, is only 15 mi. (24 km.) south of the equator, but because of its altitude of 9,350 ft. (2,850 m.) Quito enjoys a stimulating climate, the mean temperature at noon being 70° F (21° C). Carved by two ravines spanned by masonry bridges, the city, oldest of all South American capitals, preserves much of its ancient atmosphere. The towers of numerous churches outlined against a circle of volcanoes, peaceful squares, fountains, balconied houses, steep streets, iron-grilled doorways, and secluded gardens mark it as a place of charm.

Quito of the Spaniards was not a year old when the Franciscans established an art school, the first of its kind in South America. Thus began a celebrated religious art movement that flourished throughout the colonial period, leaving a wealth of polychrome sculpture in wood, and paintings without equal in the new world. Indian artists made of the churches, cloisters, and old mansions of Quito veritable museums. The names of the sculptor Manuel Chili (Caspicara), and the painters Adrián Sánchez Galque, Miguel de Santiago, and Gorívar González, among others, are noteworthy. Among the most admired Quiteño churches and convents are La Compañía (Jesuit), whose baroque columns, ceilings, and massive altars are covered with gold leaf; San Francisco, with its magnificent cloister; Carmen Alto, where the native Saint Mariana de Jesús lived and died; San Agustín, famous for carved ceilings, and Santo Domingo, noted for a handsome façade; the Sagrario, where Ecuadorean independence was declared in 1809; and the 17th-century cathedral, burial place of the hero of independence Antonio José de Sucre. Also worth mentioning is the church of the Merced convent, decorated in the Quiteño style by the contemporary Ecuadorean artist Víctor Mideros.

CAMERA PRESS—PIX FROM PUBLIX

LA COMPAÑÍA CHURCH, QUITO. CONSIDERED ONE OF THE FINEST IN SOUTH AMERICA. IS RENOWNED FOR THE GOLD LEAF THAT COVERS MUCH OF ITS INTERIOR

Although the city's convents and monasteries and its museum of colonial art indicate the deeply religious and contemplative character of its life, Quito is no longer an isolated capital, as in the past. There is a modern and busy airport meeting all international standards, including a 9,000-ft. (2,743 m.) runway required at that altitude. Quito has several daily newspapers and broadcasting stations, new housing projects for workers, and athletic fields. Factories produce everything from textiles and soap to matches, shoes, hats, soft drinks, cosmetics, ready-to-wear apparel, and pharmaceutical products. There are two institutions of higher learning, Central University founded in 1787 and the new Catholic University, offering facilities for the study of all the liberal and technical professions; also a technological institute, national library, astronomical observatory and conservatory of music. The city has several hospitals and a nursing school, two schools of social work, an American grade and high school, many modern residential developments, and good public utilities.

Ecuadoreans are proud of the *Casa de la Cultura*, a cultural centre created in 1943 and financed with a share of the export duties. It acts as publisher and distributor of the works of Ecuadorean writers and organizes concerts, lectures, art exhibits, and theatrical performances. In addition, it awards prizes for scientific research, and literary and artistic excellence.

Among the characteristic sights of Quito are several outdoor markets or fairs operating once a week in different quarters of the city. Each one has a specialty—Santo Domingo, held on Saturday, is known for furniture, and San Blas for flowers, fruits, and fowl. Only on Tuesdays, in the "24th of May" market, can one buy everything. Equally typical are the countless diminutive shops where native craftsmen make silver jewelry, religious figurines, rugs, shoes, men's suits, furniture, and other items. Although Quito is predominantly Roman Catholic there are a number of Protestant churches and a Jewish synagogue. (C. R. J.)

QUIXOTE, DON, the hero of the romance by Cervantes (q.v.), entitled *El Ingenioso Hidalgo Don Quixote de la Mancha* (pt. i, 1605; pt. ii, 1615). Originally conceived as a satire against the chivalric romances (see *SPANISH LITERATURE: The Renaissance and the Siglo de Oro: The Novel*), it describes what befalls an elderly knight who, his head bemused by reading romances, sets out on his old horse Rosinante, with his squire Sancho Panza, to seek adventure. From his name is derived the word "quixotic," used to describe someone with lofty but impracticable ideals; and one of his adventures, when he mistakes windmills for giants and attempts to joust with them, is the origin of the phrase "tilting at windmills."

QUOITS; see *HORSESHOE PITCHING*.

QUORUM, the number of members whose presence is required before a meeting can legally take action. The quorum refers to the number present, not to the number voting. The presiding officer, in determining the presence of a quorum, counts all members visible, whether voting or not; he is not required to announce the names of members so counted. A quorum is a majority unless the law, charter, constitution, by-laws, or articles creating the body fixes it at a different figure or proportion.

The term quorum came into use in the commission formerly issued to justices of the peace in England. In a day when legal scholarship on the local bench was the exception rather than the rule, it was necessary in commissioning the members of the court to add "of whom" one or two or three should be men of sufficient learning and experience to discharge the technical duties of the tribunal. These became known as the quorum, without whom the court did not sit.

The presence of a quorum is required for the transaction of all business. In the absence of a quorum, pending business is suspended and no business, however highly privileged, may be transacted even by unanimous consent. The minutes of the previous meeting cannot be read or approved without a quorum, and the point of "no quorum" may be made at any time before the reading is completed. However, prayer by a chaplain of a legislative assembly does not require a quorum, and the chair declines to entertain a point of "no quorum" before prayer is offered.

A quorum is necessary even for debate. Any member may raise the question of "no quorum" and the chair is constrained to recognize for that purpose even though another member has the floor. The absence of a quorum invalidates proceedings in which the question of a quorum was raised, and pending business retains the exact status it occupied at that time. However, if proceedings have been completed, it is too late to make the point of order that a quorum was not present.

In the absence of a quorum the meeting must either adjourn or secure a quorum. The only motions admissible are those to fix the time at which to adjourn, to adjourn, to recess, or to further the effort to secure a quorum. The previous question may be ordered on a motion incidental to securing a quorum, and an appeal from the decision of the chair is in order in that connection. A quorum is not necessary in order to adjourn, but the point of "no quorum" is in order on a negative vote on adjournment.

When a quorum is obviously present, the chair may decline to entertain a point of "no quorum" as dilatory.

As in the parent body, a majority of a standing committee is a quorum and is essential to the transaction of business. Boards of directors or trustees fall into this category. No report of a standing committee is valid unless authorized by a majority vote taken at a formal meeting of the committee with a quorum present, but it is too late to raise the question after the report has been received and taken up for consideration. Furthermore, a report adopted by a majority vote, with a quorum present, at a duly authorized meeting, is binding even though the number subsequently signing minority views outnumber those who voted for the report.

A session of a standing committee, having adjourned without securing a quorum, is *dies non* and may not be counted in determining the admissibility of a motion to reconsider. When the committee adjourns on a stated day of meeting for lack of a quorum, subsequent sessions on the same day, even when attended by a quorum, are not competent for the transaction of business.

A point of "no quorum" may be withdrawn at any time prior to ascertainment and pronouncement by the chair, but not after absence of a quorum has been determined and announced.

If it has been erroneously announced that a quorum has voted when the roll later discloses the absence of a quorum on the vote, the chair declares subsequent proceedings void.

See also *RULES OF ORDER*.

(C. CA.)

QUOTAS, IMPORT AND EXPORT, are measures that directly limit the quantity or, in exceptional cases, the value of goods or services that may be exported or imported. They stand in contrast to controls that operate by making imports or exports more expensive but without fixing a limit on the quantity; of these latter, tariffs, which put a special tax on exports or imports, are the main type.

The principal quantitative trade controls are the quota, payments restrictions (exchange controls), licensing, and monopoly systems. Under the monopoly system a governmental agency has an exclusive monopoly for the import or export of the restricted commodities. The distinction between the quota, exchange control, and licensing system is not so clear-cut. By exchange control is meant the complex of measures controlling and regulating international payments which enable a country to maintain the international value of its currency at a higher level than it would have in the absence of these controls. One of the most important of this complex of measures is the quantitative restriction of imports by quotas and licences. There is a tendency to speak of quotas when the quantities are determined in advance and the rules for the distribution of the quota among countries of origin and traders are more or less clearly formulated; and of a licence system when the granting of import licences is left to the discretion of the administrative organs. This article refers chiefly to quotas, but much of what is said holds of exchange control and licensing and monopoly systems as well.

Some quotas are fixed by autonomous action of one country while others are fixed by two or more countries operating in agreement. Another distinction is between import quotas and tariff quotas. A tariff quota is a regulation that permits the import of a certain quantity (quota) of a commodity duty free (or at a specially low duty), while quantities exceeding the quota are subjected to a (higher) duty. An absolute or import quota restricts imports absolutely. Another type is the milling or mixing quota; this is a rule requiring that imports of, say, barley must be milled or mixed in a certain proportion with home-grown grain. In the following, reference will be made chiefly to absolute import quotas.

Throughout the last quarter of the 19th century and up to 1914 the predominant method of trade control was the tariff. In the 20th century quantitative restrictions on trade were first imposed on a large scale during and immediately after World War I. During 1914 to 1918 such controls were an integral part of war economics, and for Great Britain they were imperative because of the acute shortage of shipping. After the Armistice, quotas were fairly rapidly abolished except in central and eastern Europe. There the dislocations produced by the war were much more serious than elsewhere. Trade was resumed, first, on the basis of intergovernmental barter and then on that of general prohibitions modified by licences. During the 1920s quotas were progressively abolished and replaced by tariff protection. The next great wave of quota protection of trade came with the great depression in the early 1930s. Especially after 1931 one country after another introduced quantitative restrictions, first on cereals and certain other foodstuffs and then on a great variety of agricultural and industrial products. France was the first large country to introduce a comprehensive quota system (1931), but it was followed by practically all European countries. In 1935 and 1936 there was a slight relaxation, but this movement toward somewhat freer trade soon came to an end. Everywhere economies were being geared for the approaching war; and a tightly controlled trade is an integral part of a war economy. The United States was the only important country that made very little use of quotas during the 1930s. The only significant U.S. quota was on sugar.

After the end of World War II quotas and other quantitative restrictions on imports and exports were widely used at first to

meet pressing needs of physical and currency shortages and later to maintain equilibrium in the balance of payments. In the U.S. they were used more than before the war for the purpose of restricting imports of agricultural products, especially those supported by the agricultural parity price program.

After 1955 the rapid recovery of the industrial countries of Western Europe, the restoration of confidence in their currencies, and the disappearance of the dollar shortage brought about a gradual dismantling of quantitative import restrictions by those countries. In the United States, on the other hand, somewhat more use was made of quotas for the restriction of imports (e.g., crude petroleum, lead, zinc). Textile imports from Hong Kong and Japan were restricted on a quota basis by "voluntary" agreements with those countries. Quantitative restrictions are widely used by many underdeveloped countries where open or repressed inflation prevailed. The General Agreement on Tariffs and Trade (GATT) in Geneva tried with little success to discourage the use of quantitative restrictions and to enforce an orderly, nonarbitrary and non-discriminatory administration of quantitative restrictions.

Why did quotas become so popular and how does quota protection differ from tariff protection? The increasing use made of quantitative trade controls is a phase in the trend toward autarky and protection observable from about 1878. Tariffs went higher and higher, the last free-trade countries (Great Britain, the Netherlands, Denmark) introduced protective measures, and eventually quantitative restrictions were piled on top of tariffs. But quotas are a much more effective device for restricting trade than tariffs and much more disturbing to the international trade mechanism. Under the tariff system, volume and value of trade, although restricted, are still flexible. The flow of goods changes according to changes in demand and supply at home and abroad. Despite an import duty, imports can rise if cost of production and prices fall abroad or rise at home. Thus the effect of a tariff can be offset by a depreciation of the foreign currency or by an export subsidy but a quota constitutes a rigid bar to imports. This is one of the main reasons why during the great depression of the 1930s one country after the other switched from tariffs to quotas. Tariffs were no longer regarded as sufficient protection in the face of violently changing prices, unstable currencies, and extensive utilization of export subsidies. Another related reason was that tariffs could in many cases not be increased at short notice without violating international treaties, while such treaties did not mention, and therefore were thought not to prohibit, the imposition of quotas. Quotas are a more powerful weapon of discrimination between individual countries and traders. This makes them popular with economic nationalists and protectionists in all countries. In fact, it has been practically impossible to find a method of quota allocation which could be called nondiscriminatory and in accordance with the most-favoured-nation principle, while under the tariff system nondiscrimination has a precise, generally accepted meaning. During the post-World War II period the principal motive for the use of quotas and other quantitative import restrictions was the balance of payments difficulties (dollar shortage) experienced by many countries. These problems stemmed from inflation and overvaluation of currencies.

An important characteristic of the mode of operation of quotas differentiates them sharply from tariffs. If a quota is effective, i.e., if it is smaller than the quantity which would be imported in the absence of the quota, it creates a price differential between the importing and exporting country which is not covered by transportation cost plus duty. Under the tariff system, too, the price of the taxed commodity will be higher in the importing than in the exporting country, but (except if the tariff becomes prohibitive and imports cease altogether) the price difference tends to be equal to transportation cost plus duty; if it were greater, imports would increase; if it were smaller, imports would fall until the price differential was again equal to transportation cost plus tax. Under the quota system this mechanism is eliminated. It follows that the importation of the quota-restricted commodities becomes a very lucrative business. Under the tariff system the price difference flows into the coffers of the government; under the quota system it flows into private pockets, and in all countries with

extensive quota systems fortunes have been made by importers. The consequence is that the government is forced to distribute the quota among individual traders.

When quotas were first introduced in 1931, many countries made the mistake of fixing only global quotas and of letting everybody import until the quota was exhausted. Naturally every trader tried to import at once as much as possible, and the quota was exhausted within the first few days of the period (usually a month or a quarter of a year) for which it was fixed. Distribution of the licences to import within the quota must be made according to some principle. It should be remembered that the granting of an import licence under the quota system is equivalent to the granting of an unearned income. While under the tariff system the selection of the actual importers is left to the automatic mechanism of the market and is no concern of the government, under the quota system the authorities have to decide how much each trader is allowed to import. The import function ceases to be a business activity where success depends on commercial efficiency and imagination, but becomes a sinecure handed out by government agencies. In the 1930s, the usual procedure was to distribute quotas among countries of origin and individual traders (usually importers but sometimes also foreign exporters) in proportion to the imports from the respective countries effected by the individual traders in some base period which was considered as "normal." It is easy to see that this is not a satisfactory solution and that it becomes less and less satisfactory as time goes on and the underlying situation changes. But the fact that quotas give rise to large profits, made in connection with imports and exports, has made the system popular with importers and exporters. This popularity is enhanced by the fact that quota restriction, much more than tariffs, facilitates monopolistic price policies by domestic producers. All these unavoidable abuses, inefficiencies, and inconveniences made it unlikely and undesirable that the quota system would replace the tariff system.

See EXCHANGE CONTROL; MOST-FAVOURLED-NATION TREATMENT; TARIFFS.

QUO WARRANTO was originally a writ by means of which the English crown commenced a civil proceeding to determine "by what authority" a person exercised a right to a franchise or office, including the title to real property. Thus, Edward I used it widely to establish the right to lands under his dominion. Later, it became a writ criminal in nature used not only to oust a usurper from office but to punish him as well. Long before the American Revolution, however, it had reverted to a civil claim to try the right to office and could be brought not only by the crown but by any interested party. In the United States, the action of *quo warranto* is governed largely by statutes which vary widely from jurisdiction to jurisdiction. It is used primarily for the purpose of testing the right to exercise public or corporate office and to assay the validity of the exercise of authority by local governmental bodies and corporations. In England, proceedings by way of injunction have taken the place of proceedings by way of *quo warranto*. (P. B. K.)

QUTB UD-DIN AIBAK (d. 1210), general of Mohammed of Ghor (q.v.) and a founder of Muslim rule in India, was brought in childhood from Turkistan to be sold as a slave. Qutb ud-Din was brought up at Nishapur by Qazi Fakhr ud-Din Kufi before coming into the possession of Mohammed of Ghor who promoted him to be *amir-i-akhur* in charge of the royal stables. Eventually

he was appointed to the military command of Kuhram (in the former Patiala state) captured from the Chauhanas after their defeat at the second battle of Tara'in in 1192. During Mohammed of Ghor's absences, Qutb ud-Din acted as the principal Ghorid commander in Hindustan. Establishing his headquarters at Delhi about 1193, Qutb ud-Din subjugated areas between the Ganges and the Jumna before joining Mohammed of Ghor in defeating the Gahadavala ruler, Jaichand, at Chandawar in 1194. Despite this important victory, Rajput opposition to the Turks was far from overawed and campaigns followed in swift succession against Ajmer (1195), Anhilwara (1197), Bada'un (1197-98), Kannauj (1198-99) and Kalinjar (1202-03). After the assassination of Mohammed of Ghor in 1206, Qutb ud-Din moved to Lahore and

assumed power there. He was not, as is sometimes stated, the founder of an independent Delhi sultanate. Surviving inscriptions describe him as no more than *malik* or *sipahsalar*. Until his death in 1210 from injuries received in a game of *chaugan* (a kind of polo), he kept his headquarters at Lahore. In 1208, he occupied Ghazni, only to be expelled by a rival, Yilduz. Although Qutb ud-Din apparently made no attempt between 1206 and 1210 to consolidate and extend the earlier Ghorid conquests in Hindustan proper, it was his leadership, generalship and loyal service to Mohammed of Ghor that made it possible for Iltutmish to establish the independent sultanate of Delhi (*q.v.*).

See A. B. M. Habibullah, *The Foundation of Muslim Rule in India*, 2nd rev. ed. (1961). (P. H.)

R THE letter corresponding to modern R in the ancient Semitic alphabet was 𐤓 (*resh*), perhaps deriving from an earlier sign representing a head. Greek *rho* is found in a form practically unchanged in the early inscriptions from the island of Thera. The same form also occurs in early inscriptions from Attica and Corinth and in the Chalcidic alphabet. The most usual Greek form was rounded P; this is the form in which the letter occurs in the Lydian alphabet. A form D in which the loop is extended to the bottom of the vertical stroke also occurs in both the eastern and western alphabets. This was the form of the letter in the Umbrian and Oscan alphabets of Italy, while Etruscan had a form in which the loop reached nearly to the bottom. In the Chalcidic alphabet a form R with an additional oblique stroke occurred, and this must be the ultimate source of the Latin form, in which the oblique stroke was exaggerated.

The minuscule form has been subject to many variations. In cursive Latin of the 6th century occurred a form V in which the loop has disappeared, the three right-hand oblique strokes, or the loop and oblique stroke, being reduced to a single stroke. The Irish form in the 7th century was R in which a similar process had taken place, but the remnants of the loop and oblique stroke had become extended in a horizontal direction. On the basis of this was formed the Carolingian R, in which the vertical stroke was not extended below the line. The Carolingian form is the minuscule R of modern printing, but in handwriting it still contends with the form R, resembling the Latin cursive tradition.

The sound represented by the letter has been in general the liquid formed by contact between the tip of the tongue and the palate, but its precise quality differs considerably from one language or dialect to another. The trilled r produced by rolling the tip of the tongue, is found not only in several continental languages but in certain dialects of English as well. The back or uvular r is characteristic of standard French and is current in many parts of Germany. In southern England and the eastern United States the r is feebly pronounced and in final position is

often dropped altogether. The spelling with initial rh is practically limited to words of Greek origin (e.g., rhetoric), where it represents the classical Greek writing of rho with a rough breathing (ρ̑) to indicate an unvoiced pronunciation. It has intruded itself incorrectly in "rhyme" (for "rime") and in "Rhegium," "Rhaetic." (B. F. C. A.; J. W. P.)

RAABE, WILHELM (1831–1910), German novelist, an important representative of middle-class realism in the second half of the 19th century, was born on Sept. 8, 1831, in Eschershausen, near the Weser, in Lower Saxony, the son of a lawyer. After four years' apprenticeship to a bookseller in Magdeburg, he studied at Berlin university for two years (1854–56). It was as a student that he became conscious of his gift for writing and from that time he lived as an independent writer in Wolfenbüttel, Stuttgart (1862–70) and finally in Brunswick, where he spent the last 40 years of his life and where he died on Nov. 15, 1910.

Raabe's philosophical and artistic development was as complicated as, externally, his life was unremarkable. His early writings show traces of classical and romantic influence and are sentimentally idealistic. They include *Die Chronik der Sperlingsgasse* (1857), the historical novel *Unseres Herrgotts Kanzlei* (1862) and two novels showing the evolution of character, *Die Leute aus dem Walde* (1863) and *Der Hungerpastor* (1864; Eng. trans. 1885). His book *Drei Federn* (1865) was the beginning of a new creative period which reached its peak in the great contemporary novels *Abu Telfan* (1868; Eng. trans. 1881) and *Der Schüdderump* (1870). In the novels of this period Raabe's realistic, often satirical, attitude was an attack on the illusions with which the middle classes glossed over the questions of human existence and of the contemporary social order. The human situation then appeared to him as basically tragic, and he approached, independently, the pessimism of Schopenhauer, without, however, sharing his skepticism.

In his third period, which began in the middle of the 1870s, Raabe found the strength to accept human existence in spite of its unsatisfactoriness. This position grew out of ethical conviction, sustained by sympathy and helpfulness, and expressed itself in the creation of figures representative of fundamental human potentialities. This reconciliation with the world found its happiest expression, from the literary point of view, in humour. Formally speaking, the once prominent realism of his writing deepened to a symbolic realism through an illumination of the essential. Notable works of this last period are *Horacker* (1876), *Alte Nester* (1880), *Das Horn von Wanza* (1881), *Unruhige Gäste* (1886), *Das Odsfeld* (1889), *Stopfkuchen* (1891) and *Die Akten des Vogelsangs* (1896).

RAB (Ital. ARBE), an island in the Adriatic Sea forming the northernmost point of Dalmatia, Yugos. Pop. (1961) 8,369. Rab is 13.3 mi. (21.4 km.) long; its greatest breadth is 6.8 mi. (10.9 km.). The capital of the same name is one of the best-known Yugoslav seaside resorts, a walled town of rare charm on the steep ridge of the west coast. At the seaward end is the 13th-century cathedral in Romanesque style, behind which the belfries of four churches rise in a row along the crest of the ridge. Behind these again are the castle and a background of desolate hills. The island also has six villages. Agriculture and fishing are the main occupations. Rab was the birthplace of Marco Antonio de Dominis (d. 1624), the Italian theologian.

RABAH ZUBAYR (ZUBEIR) (d. 1900), the conqueror of Bornu (an ancient sultanate on the western shores of Lake Chad, included since 1890 in Nigeria), was a half-Arab, half-Negro chief.

DEVELOPMENT OF LETTER "R" FROM EARLIEST TIMES TO THE PRESENT

tain and originally a slave or follower of Zubayr Pasha Rahma Mansur. In 1879, Zubayr being in Egypt, his son Suleiman and Rabah were in command of Zubayr's forces in the Bahr el Ghazal. They persisted in slave raiding, and denied the khedive's authority. Col. (later Gen.) C. G. Gordon, governor general of the Sudan, therefore sent against them Romolo Gessi Pasha. Gessi captured Suleiman and routed Rabah, who in July 1879 fled westward with some 700 Bazingirs (black slave soldiers).

He made himself master of Kreich and Dar Banda, countries to the south and southwest of Wadai. He finally established himself in Baguirmi, a state southeast of Lake Chad. In 1893 Rabah overthrew the sultan of Bornu. In his administration of the country he showed considerable ability and a sense of public needs. To the British, represented by the Royal Niger Company, Rabah gave comparatively little trouble. Early in 1897 he began an advance in the direction of Kano, the most important city in the Fulani Empire. The news of the crushing defeat by Sir George Goldie of the Fulani at Bida induced Rabah to return to Bornu. He now turned his attention to the French. Émile Gentil had in this same year (1897) reached Lake Chad, via the Congo and Baguirmi, and had installed a French resident with the sultan of Baguirmi. As soon as Gentil had withdrawn, Rabah again fell upon Baguirmi and forced sultan and resident to flee. In 1899 the French sent an expedition to reconquer the country, but it was only after a third encounter (April 22, 1900) that Rabah was slain and his host defeated. The chieftain's head was cut off and taken to the French camp.

The French continued the campaign against Rabah's sons, two of whom were killed. Rabah had left instructions that if his army was finally defeated by the French, his successor should return to Bornu and make friends with the British. Rabah's third son, Fader-Allah, accordingly threw himself entirely upon British protection. But in the later part of 1901 Fader-Allah, who had 2,500 riflemen, again made aggressive movements against the French. In retaliation, French forces pursued him into British territory. A battle was fought at Gujba, Fader-Allah being defeated. He fled mortally wounded and died the same night.

RABANUS (HRABANUS) MAURUS, MAGNENTIUS (780-856), abbot of Fulda and archbishop of Mainz, one of the leading teachers of the Carolingian period, was born at Mainz in 780. From the school at Fulda he went to study at Tours under Alcuin, who called him Maurus after St. Benedict's favourite disciple. His passion was the accumulation of knowledge, and he became the head of the school at Fulda, where he greatly increased the library. He was made abbot in 822, but resigned in 842 for personal and political reasons, only to become in 847 archbishop of Mainz, where he died on Feb. 4, 856.

In all his numerous writings Rabanus did not attempt to be original but was content from his great range of reading to use the work of others. So his encyclopaedic *De naturis rerum* owes almost everything to Isidore of Seville, and his massive commentaries for students and teachers on various books of the Bible are based on material taken from the Church Fathers. The same is true of his collection of homilies, his influential educational work *De institutione clericorum* and his verse as a whole. His *De laudibus sanctae crucis* contains a number of ingenious *carmina figurata* (verse in which the lines are superimposed on a drawing so that the individual letters along the outline of the drawing can be read to form further words or sentences). Rabanus' one poem not in quantitative metre incorporates, with adaptations, Columba's *Altus prosator*. There is no evidence for attributing the hymn *Veni, creator spiritus* to Rabanus. Rabanus' importance rests on his merits as a teacher and on his encouragement of the study of the ancient authors, though always for Christian ends. He was deservedly called *praeceptor Germaniae*, for under him Fulda became a rival of Tours.

RABAT, the political capital of the kingdom of Morocco, North Africa, lies on the Atlantic coast, at the mouth of the Bou Regreg, 57 mi. (92 km.) NE of Casablanca and 174 mi. (280 km.) SW of Tangier by road. Rabat, on the south bank, is separated by the Bou Regreg from the town of Salé (Sla) opposite. Pop. (1960) 227,445; of whom 182,295 were Muslim, 11,008 Jewish, and 34,142 non-Moroccan.

The old town, still surrounded by ramparts, lies near the coast, from which it is separated by a hill covered with extensive cemeteries. Within the ramparts are the *medina*, or ancient Muslim town, and the *mellah*, or Jewish quarter. To the north stands an ancient fortress, the Kasbah des Oudaya (Oudaia), on a cliff above the mouth of the Bou Regreg; it is entered by a splendid 12th-century gateway built during the dynasty of the Almohads (q.v.). The Kasbah has a charming Andalusian garden and the adjoining medersa (college) houses a museum of Moroccan art. Southeast of the old town, dominating the valley, is the 12th-century Hassan Tower, a magnificent minaret of the Almohad period, at the foot of which are the ruins of the mosque of Al-Mansur. Intended to be the biggest in the world, it was never completed.

The modern quarter of Rabat is partly enclosed within a great fortified wall which still stands along the greater part of its perimeter. In the south, the fortifications surround the Dar Al Makhzen, or Sultan's palace, in front of which is the *Mechouar*, an immense walled courtyard, once bare, but laid out at the end of the 19th century with lawns. It was there that the sovereign received homage from his subjects. Various administrative buildings, among them the supreme court of justice, are in this part of the town, and nearby is Bab Ar Rouah, or the gate of the winds, a beautiful Almohad gateway. A summer palace, the Dar As Salam, was built 4 mi. (6 km.) S of Rabat by Mohammed V in the 1950s.

Most of the government buildings are situated on the slopes of a hill around the former residency general, which is now the French embassy. The residential districts of Orangers and Aguedal, consisting of villas surrounded by gardens, extend far beyond the Almohad walls.

The port was never busy because its approach was obstructed by the sandbar outside and by the constant silting up of the channel. The harbour has been abandoned and a bridge, completed in 1957, links Rabat with Salé, making it impossible for ships to enter. Rabat has a modern textile industry and is noted for its carpets and *hanbels* (blankets). Vegetables and fruits are preserved for export, and there are factories producing bricks, asbestos, and fish cakes.

History.—The town's history is inseparable from that of Salé. The first settlement was the Roman town of Sala Colonia, the remains of which were excavated in 1930 near Chella to the south of the city. These ruins adjoin the tombs of the Marinid (Banu Marin) dynasty (14th century). The present town of Salé was established between the 10th and 11th centuries and was founded by the Zenata Berbers, who were orthodox Muslims, to house the heretical Berghouata Berbers, whose domain stretched from the Bou Regreg west to the Oum Ar Rebia during the 10th and 11th centuries. The Kasbah, later called "des Oudaya," was in the first place a bridgehead on the south bank for the occupants of Salé, and was for a long time called Salé-le-Neuf.

In the 12th century the first Almohad sultan, Abd-al-Mumin, built a *ribât* (camp), where he concentrated troops for his religious war in Spain. His second successor, Yakub al-Mansur, called it *Ribât al-Fath*, "the camp of victory," from which the town of Rabat takes its name. He erected the great fortified wall, within which the modern town has developed, as well as the tower of Hassan. In the 17th century numbers of Moors driven from Spain (the *Hornacheros*) settled in Rabat, which became with Salé a Corsair republic. These "Sallee-rovers" preyed initially on Spanish shipping but ultimately terrorized the Atlantic seaboard. (See BARBARY PIRATES.)

The Filali (Alaouite) sultans, who stopped in Rabat on their way from Fès to Marrakesh, had a palace built there in the 17th century. Under the French protectorate (1912-56), Rabat was made the capital of the country. Following Moroccan independence, Rabat was one of two cities to be created independent

prefectures (the other being Casablanca).

Rabat province (pop. [1960] 1,156,555) mainly occupies the Al Gharb coastal plain and the western foothills of the central plateau. Salé (pop. 75,779) is the administrative capital.

See H. Terrasse, *Villes impériales du Maroc* (1937); R. Coindreau, *Les Corsaires de Salé* (1948); J. Caillé, *La Ville de Rabat jusqu'au Protectorat français*, 3 vol. (1949). (A. Am.)

RABAT SKULL, belonging to Rabat man, a North African pre-Neanderthal, was discovered in 1933 in a quarry in a suburb of Rabat, Mor. Recalling Neanderthal man (*q.v.*) by certain traits, *Sinanthropus* (*q.v.*) by others, it was found in the upper part of a thick layer of sandstone, which contained also *Elephas atlanticus*; Chelleo-Acheulean stone tools were found in another part of the pit. These Rabat sandstones are considered as dating from the third or perhaps even the second interglacial epoch; the age of the skull could therefore be about 200,000 years. The skull, broken before its discovery and very incomplete, is represented by the anteroinferior part of the face. It has a very high and remarkably wide palate and a very robust jaw with no chin. The very large teeth have a great many primitive characteristics, the most important being the presence of a basal bulging, or cingulum, on the molars and premolars.

The paleoanthropological discoveries later made in the same region, at Sidi Abderrahman and Temara, have brought new arguments in favour of the existence of this human fossil group, which seems to have evolved independently of its European contemporaries. See also MAN, EVOLUTION OF.

See M. Boule and H. V. Vallois, *Fossil Men* (1957). (H. V. V.)

RABAUT, PAUL (1718–1794), French Protestant minister who succeeded Antoine Court as leader of the “church of the desert” (see HUGUENOTS: 18th Century), was born at Bédarieux, Hérault, Jan. 29, 1718. In youth he acted as a guide to the ministers who held secret meetings in the Cévennes. In 1738 he became an exhorter at Nîmes and married there. He studied theology at the college founded by Court at Lausanne and returned as minister to Nîmes, about 1743, becoming vice-president of the general synod of the Reformed Church in 1744. But the *dragonnades* (see HUGUENOTS: 17th Century) recommenced after the end of the War of the Austrian Succession, and Rabaut went into hiding under various disguises and aliases with a price on his head. He sustained the Protestants, conducted a vast correspondence (preserved in the National Library at Geneva and only partially published) and, like Court, sought to prevent armed rebellion by the Protestants. The government tried to persuade Rabaut to leave France, but he refused, seeking, through his influence with high officials, to reduce persecution. The Calas affair and its consequences brought alleviation of the Huguenots' suffering (see CALAS, JEAN), and in November 1787 Louis XVI signed an edict of toleration. Rabaut crowned his efforts by dedicating the new church at Nîmes in 1792. His eldest son, Jean Paul Rabaut-St. Étienne (1743–93), president of the revolutionary National Assembly (1790), was killed in the Terror, and Rabaut himself died on Sept. 25, 1794, at Nîmes after a brief imprisonment. (B. H.)

RABBI (Hebrew “my master” or “my teacher”), **RABBAN** or **RABBENU** (“our master” or “our teacher”) and **RAB** (“master” or “teacher”) are titles applied to Jewish scholars or teachers. The title *rabbi* first came into general use toward the end of the 1st century A.D., although the heads of the Sanhedrin (*q.v.*) had borne the title *rabban* since the time of Gamaliel I. Scholars who received their ordination in Palestine were called *rabbi*, while the Babylonian scholars who were not ordained in Palestine were called *rab*.

The title *rabbenu* was applied to Judah the Prince, the codifier of the Mishna (2nd–3rd century A.D.), and since then it has been a title designating the outstanding scholars of every generation.

There is no sharp distinction in religious status between the *rabbi* and the layman in Judaism. The *rabbi* is simply a layman specially learned in the Scriptures and the Talmud. To be recognized as a *rabbi*, however, a talmudic student has to be ordained. The custom of ordination is very old.

Joshua was ordained by Moses, the ceremony being as follows: Moses placed Joshua before Eleazar and the congregation and

laid his hands upon him while giving him instructions. Symbolically, a portion of the spirit of Moses was transferred to Joshua through Moses' hands.

Moses also ordained the 70 elders who assisted him in governing the people. According to tradition the elders ordained their successors, who in turn ordained others, so that there existed an unbroken chain of ordination down to the time of the Second Temple.

The practice of ordination in its Mosaic form ceased in Palestine in the second half of the 4th century when the Judaean academies were closed. (In the 16th century an attempt was made in Palestine to revive the ancient ordination, as well as the Sanhedrin, with all the power and authority that it possessed, but this attempt resulted in failure.) Down to the end of the 14th century, rabbinic ordination was purely a verbal ceremony. Later a new procedure was introduced whereby ordination was conferred upon a candidate in the form of a written statement awarded by a well-known and recognized scholar. Traditionally, the authority to act as a *rabbi* may be conferred by any other *rabbi*, but it is usual for students in theological academies to receive this authority from their teachers. In America the best-known rabbinical schools that ordain graduates are: the Hebrew Theological college, Skokie, Ill. (Orthodox); the Hebrew Union College-Jewish Institute of Religion, Cincinnati-New York city (Reform); the Jewish Theological Seminary of America, New York city (Conservative); and the Rabbi Elchanan Theological seminary, New York city (Orthodox). The main associations of U.S. rabbis are the Central Conference of American Rabbis (Reform), the Rabbinical Assembly of America (Conservative) and the Rabbinical Council of America (Orthodox).

In the middle ages there was strong opposition toward the chief rabbis, who usually were government appointees rather than persons chosen by the Jewish communities. The office of the chief *rabbi* exists today in some western European countries and in Israel. In England the chief *rabbi* of the United Hebrew Congregations of the British Commonwealth of Nations is elected by representatives of the congregations in Great Britain and the British dominions. He is thus recognized as the spiritual head of the majority of Jews in the British Commonwealth. The first chief *rabbi* of England was Rabbi David Tebele Schiff (1765–92).

In France the office of the chief *rabbi* goes back to the Napoleonic consistorial system of 1808.

In Israel the chief rabbinate is based on the Religious Community ordinance of 1926, which conferred religious authority upon the rabbinical council headed by two chief rabbis, one belonging to the Sephardic, the other to the Ashkenazic section of the Jewish community.

See Louis Finkelstein, *The Beliefs and Practices of Judaism*, rev. ed. (J. M. RL.) (1952).

RABBIT, any member of the mammalian family *Leporidae* (order *Lagomorpha*) whose young are born naked, blind, and helpless in a furred nest. They are generally smaller than hares, although some rabbits, especially of the many domestic breeds, are very large. Collectively, rabbits are not sharply separated from the hares structurally, but in any given region local species of the two groups may differ significantly. (See HARE for points of difference.)

The typical rabbit is the European *Oryctolagus cuniculus*, the so-called Belgian hare or domestic rabbit. Seemingly in early times this species occurred over central Europe north of the Mediterranean region, from Ireland to western Russia, and in north Africa. It has been raised domestically for centuries, however, and has been introduced and established in many parts of the world. It is an exceedingly prolific animal, having no fixed periodicity to the breeding cycle. Females, or does, begin breeding when about eight months old. Gestation lasts about 30 days, and the female may breed again very shortly after producing a litter. The number of young varies with the breed and age of the female, but six to nine kittens or bunnies to a litter is about average. Ovulation is caused by coitus; when coitus does not result in pregnancy, a pseudopregnancy ensues, at which time the mam-

mary glands are in condition for lactation and the doe constructs a nest. The doe cares for the young, the buck offering no assistance.

In the wild the European rabbit inhabits brushy fence rows and thickets from which it ventures into the fields to feed in the evening and night. It is a social animal, living usually in colonies but evincing only a weakly developed social system. It possesses a placid and timid temperament. As is true of many other kinds of small mammals, the density of rabbit populations undergoes extreme cyclical fluctuations.

The common North American rabbits, which belong to the genus *Sylvilagus*, are generally called cottontail rabbits. The marsh cottontail (*S. palustris*) and the swamp cottontail (*S. aquaticus*) occur in swampy areas in the southeastern United States. Both have short, thin hair. The eastern cottontail (*S. floridanus*) ranges over the United States east of the Rockies and southward to Costa Rica; occupying a wide variety of habitats and a large geographic range, it is a highly variable animal. Nuttall's cottontail (*S. nuttallii*) replaces the eastern cottontail in western North America, and extends from southern Canada to central Arizona. Audubon's cottontail (*S. audubonii*) is another western species, extending from Montana to central Mexico. Other rabbits occupy generally more restricted areas and some extend into South America, where the large Patagonian rabbit is found. Rabbits of several species are also found in Asia, South Africa and on some islands.

Rabbits are of considerable economic importance. They are important as buffer species and form the bulk of the diet of many predators. They act as reservoirs and hosts of pathogenic organisms such as those causing tularemia (*q.v.*), which can be transmitted to man. In some areas they become serious pests because of their depredations on cultivated crops or grazing lands. Australia is a notable example. After several attempts at introduction, man successfully established rabbits in the late 1800s, but the animals bred prodigiously and soon overran the continent despite costly control measures. The successful establishment of the virus disease myxomatosis in Australia in the early 1950s acted as a great brake on the rabbit population; however, the appearance of rabbits resistant to the disease raised doubts of the continued effectiveness of the virus in controlling their increase. Australia is still a principal source of the rabbit fur used commercially.

Rabbits are the most widely hunted small game animal wherever they occur. Hunters usually use small dogs such as beagles to find and flush the rabbits from cover. In Europe ferrets are trained to drive the rabbits from their burrows. Rabbits are most

LEONARD LEE RUE—ANNAN PHOTO FEATURES

VARYING HARE (*LEPUS OTHUS*)

often hunted in the colder seasons. Rabbit fur (sometimes called lapin) is used in great quantities in the fur industry although the pelts are fragile. The soft, delicate fur is plucked, trimmed and dyed to simulate more valuable furs, frequently seal and chinchilla. Many unusual varieties of the European rabbit have arisen during domestication by man. Among the popular kinds as pets and as fur bearers are the Flemish giant, New Zealand white, silver gray, chinchilla, Havana, American blue, Dutch belted and Angora. The silky, white hairs of the Angora rabbit (so named for the resemblance of its pelt to that of the Angora goat) often measure seven inches long and are used in fine, fluffy woolen yarns. The fur of other rabbits is the main source of felt, and the delicately flavoured flesh is excellent to eat. Because of the ease with which they are reared in captivity, rabbits are important as laboratory animals, both in experimental work and in certain diagnostic medical tests.

RABBULA (d. A.D. 435), bishop of Edessa (411–435), was a leading figure in the Syrian Church. At first a follower of Antiochene theology, in 432 he became an ardent supporter of Cyril of Alexandria, whose *De recta fide* he translated into Syriac. He initiated aggressive action against the representatives of Antiochene theology in the school of Edessa. His canons made an important contribution to ecclesiastical legislation. He also wrote a homily against Nestorius, and of his letters one to Andrew of Samosata and excerpts of those to Cyril and to Gemellinus of Perrhae have survived. The hymns attributed to him are of dubious authenticity. The surviving remains of the biblical text of Old Syriac provenance which Rabbula employed prove that he was not the author of the Peshitta as has been generally thought. He died in Edessa on Aug. 7, 435. See also EDESSA; Edessene Christianity; SYRIAC LITERATURE.

RABELAIS, FRANÇOIS (c. 1494-1553), French writer, who for his contemporaries was an eminent physician and humanist, and for his posterity is the author of a comic and satirical masterpiece, *Gargantua et Pantagruel*, which sought to liberate the late Middle Ages from the shams and superstitions that imprisoned the natural man.

Life and the Genesis of His Work.—The date of his birth is uncertain; tradition and the scholars who have worked on the problem place it as either 1483, 1490 or 1494. A manuscript epitaph in the church of St. Paul, Paris, dates his death as April 9, 1553, at the age of 70; if, as is probable, this date is exact it would indicate that he was born in 1483. But various indications in his work, in his life and above all his use of the term "adolescent" in a letter of 1521 to Guillaume Budé, do not allow that the date of birth should be placed before 1494. He was born at La Devinière, a farm in the parish of Seuilly not far from Chinon in the province of Touraine. This is based on a local tradition unearthed in 1699 by a scholar named Roger de Gaignières, a tradition verified by modern scholarship and from scattered allusions in *Gargantua et Pantagruel* itself. His father, Antoine Rabelais, bachelor of law and advocate at the royal court of justice at Chinon, owned a town house as well as La Devinière and other country properties; this house (the present no. 15, Rue de Lamproie) became a tavern about 1590, whence the legend, later put in circulation, that Rabelais was the son of an innkeeper. An unverifiable tradition claims that he was sent as a child to the

convent of Seuilly; at an unknown date tradition takes him to the convent school of La Baumette near Angers—but in all this nothing is certain. He certainly entered the Franciscan friary of Fontenay-le-Comte, and he must have been there during the last six months of 1520, because during the month of October in that year he had written, on the advice of his companion in study, the friar-minor Pierre Amy, a letter (now lost) to the famous scholar Guillaume Budé (q.v.). Rabelais wrote a second letter to Budé, dated March 4, 1521, persuaded, as he says, that Budé would interest himself in an "adolescent" who, however unknown, was passionately devoted to literature; the autograph of this letter is extant, perhaps the only one certainly in his own hand. He was also in communication with Amaury Bouchard, president of Saintes, and he frequented the learned circle which met at the house of the lawyer André Tiraqueau. Toward the end of 1524, or at the beginning of 1525, Rabelais, who had made up his mind to devote his life to study and writing, petitioned Pope Clement VII to grant him leave to be transferred to the Benedictines, which he obtained. He then became secretary to Geoffroy d'Estissac, abbot and bishop of Maillezais, and perhaps tutor to his nephew Louis also; he remained in this post until 1527. Geoffroy d'Estissac resided in his see, either at the priory of Ligugé or at Coulonges-les-Royaux, but for the most part he traveled about his diocese and visited his abbeys in Poitou and Périgord. Rabelais accompanied him on these journeys, and, curious about all he saw, was an amused observer of village and peasant life; he began to collect the legends, proverbs, and rustic words that give such a tang to his writings. At the same period he allied himself in friendship with the *rhétoriqueur* Jean Bouchet of Poitiers and Antoine Ardillon, abbot of Fontaine-le-Comte; doubtless he was already interesting himself in medicine. But even this studious existence based on Maillezais did not satisfy him. About 1528, after visiting Bordeaux, Agen, Toulouse, Bourges and Orléans, he went to Paris where he was lodged at the Hôtel

SERVICE DE DOCUMENTATION PHOTOGRAPHIQUE
FRANÇOIS RABELAIS. LATE 17TH-CENTURY PORTRAIT BY AN UNKNOWN ARTIST; IN THE MUSÉE DE VERSAILLES

Saint-Denis, a house of study belonging to the Benedictines. In 1530 he cast aside his monk's habit without leave of his superiors and, as a secular priest, entered in the faculty of medicine at Montpellier on Sept. 17; so high was the opinion of his attainments that he became bachelor on Dec. 1. Early in 1531 he gave public lectures on Galen and Hippocrates. After a short stay in Poitou (probably the autumn and winter of 1531-32) he went to Lyons in June 1532. Sometime before the beginning of winter he was appointed physician to the Hôtel Dieu in Lyons, with a salary of 40 livres per annum, and lectured on anatomy with demonstrations from the human subject. In the same year (1532) he edited for Sebastian Gryphius the medical *Epistles* of Giovanni Manardi, the *Aphorisms* of Hippocrates, with the *Ars Parva* of Galen, and an edition of two Latin documents which, however, turned out to be forgeries.

At this time Lyons was the centre of an unusually enlightened society which welcomed Rabelais as an intimate. A manuscript distich of Jean de Boyssonné (in the library of Toulouse) mentions the death of an infant named Théodule, whose native place was Lyons and whose father's name was Rabelais, but nothing more is known of this matter. Rabelais had had two other children by an unknown woman while in Paris between 1528 and 1530; they were named François and Junie, and a petition for their legitimacy was presented to Pope Paul III on Jan. 9, 1540.

What makes the Lyons sojourn of the greatest importance is that at this time probably appeared the beginnings of the work which was to make Rabelais immortal. In 1532, perhaps at the beginning of August, a book called *Les Grandes et inestimables chroniques du grand et énorme géant Gargantua* made its appearance at Lyons. This is a short book (of which there are several versions) having similarities to the later burlesques and romances of the Round Table. Arthur and Merlin appear with Grandgosier, as he is here spelled, Galemelle (i.e., Gargamelle), Gargantua himself, and the terrible mare. But as yet there is no trace of the action or other characters of the *Gargantua* that was to come, nor is the style in the least worthy of Rabelais.

The popular tales in this chapbook of 1532 that recounted the deeds of "the enormous giant Gargantua" are probably anterior to the period when they were written down, and thus belong to oral tradition. Countless place-names in France refer to the name of Gargantua, the voracious giant to whom are ascribed the various Gargans or Garganos, cult-centres of St. Michael, as well as the Spanish and Languedocian *garganta* (throat) and *gargantuan* (glutton). The only written and dated evidence of the name before Rabelais' time is to be found in the account books of the bishop of Limoges at St. Léonard in 1471, in which a certain Gargantua is mentioned, a friend of the prelate—and this is clearly a nickname. These popular stories served as nothing more than an outline for Rabelais, and he used them with complete freedom. The first book of *Pantagruel* (the second of the whole work) was composed with the chapbook of 1532 in mind and not in relation to the existing first book of *Gargantua* which was written subsequently, after Rabelais had discovered the popularity of his work and felt that it ought to have some worthier starting point than the *Grandes Chroniques*. *Pantagruel*, in popular tradition, is an imp whose name can be found in many *mystères* of the period, among others the *Mystère des Actes des Apôtres* of Simon Gréban. The imp's particular role was to make men thirsty and force them to drink. There must often have been allusions to him in the torrid summer of 1532—one of the most terrible ever to have been endured, according to contemporary chroniclers: "Pantagruel," people said, "has us by the throat." The earliest edition of *Pantagruel* appeared in the first days of November 1532, and of *Gargantua* in 1534, but this would not of itself be conclusive: the definite description of Gargantua in the title as *Père de Pantagruel*, the omission of the words "second livre" in the title of the first book of *Pantagruel* while the second and third are duly entitled "tiers" and "quart," the remarkable fact that one of the important personages, Friar John, is absent from Book II, i.e., the first book of *Pantagruel*, though he appears in Book I (*Gargantua*), and many other proofs show the order of publication clearly enough. It is also significant that in 1533 there was published

an almanac, the first of a long series which exists only in titles and fragments, and the amusing *Pantagrueline Prognostication* (still, it is to be observed, *Pantagrueline*, not *Gargantue*), republished in 1535. Both this and *Pantagruel* itself were published under the anagrammatic pseudonym of "Alcofribas Nasier," shortened to the first word only in the case of the *Prognostication*.

On Oct. 23, 1533, *Pantagruel* was condemned by the Sorbonne as obscene, and in January 1534 Jean du Bellay (*q.v.*), passing through Lyons on an embassy to Rome, engaged Rabelais to accompany him as physician. This visit did not last long (Feb. 2–April 1), but it left literary results in an edition of a description of Rome by Bartolomeo Marliani which Rabelais published in September 1534. However the "affair of the placards" against the Mass, which occurred in Paris on the night of Oct. 17–18, provoked severe measures against those suspected of Lutheranism. Rabelais judged it prudent to leave Lyons for an unknown destination (Grenoble or Poitou) on Feb. 13, 1535, without announcing the fact.

On March 5, 1535, the authorities of the Lyons hospital, considering that Rabelais had twice absented himself without leave, elected Pierre de Castel in his place; but the documents do not imply any blame and the appointment of his successor was at one time definitely postponed in case he should return. In July 1535 Rabelais once more accompanied Jean du Bellay, now a cardinal, to Rome, passing through Ferrara where he met Clément Marot (*q.v.*); he remained at Rome until April 11, 1536. To this period belong letters to Geoffroy d'Estissac and a *Supplicatio pro Apostasia* (Dec. 10, 1535) and the Bull of Absolution which was the reply to it. This bull freed Rabelais from ecclesiastical censure and gave him the right to return to the Order of St. Benedict when he chose, and to practise medicine. He took advantage of the bull and became a canon of Saint-Maur, of which Jean du Bellay was the dean. It was not long before he began his wandering life once again, going to Montpellier where he received his licentiate (April 1537) and doctorate (May 22, 1537); he practised at Narbonne and Lyons and delivered a course of lectures at Montpellier on the Greek text of the *Prognostica* of Hippocrates from Oct. 18, 1537, to April 14, 1538. On July 14, 1538, he was present at the conference between Francis I and Charles V at Aigues-Mortes. He went to Italy for a third time in 1540, on this occasion in the service of Guillaume du Bellay (*q.v.*), elder brother of Jean, who was governor of Piedmont; according to the letters of Pellicier, bishop of Montpellier and ambassador to Venice, Rabelais was then employed by him to collect manuscripts for the king's library. In the autumn of 1540 he was compelled to clear himself of the charge of having revealed diplomatic secrets, but he remained at Turin in the service of Guillaume du Bellay until the latter died on Jan. 9, 1543. Rabelais wrote a panegyric memoir of Guillaume, which is lost. In the previous year an edition in which *Gargantua* and the first book of *Pantagruel* formed a single volume (both had been repeatedly reprinted separately) was published, and in this edition certain dangerous expressions were excised. Nothing at all is known of Rabelais' life, whereabouts, or occupations from 1543 until the publication of Book III which appeared in 1546 *avec privilège du roi* (granted in September 1545).

Up to this time Rabelais, despite the condemnation of the Sorbonne, had experienced no persecution or trouble. Even the action of Étienne Dolet (*q.v.*), who in 1542 reprinted the earlier form of the books which Rabelais had recently modified, seems to have done him no harm.

But religious intolerance, which toward the end of the reign of Francis I was fatal to Dolet himself and to Bonaventure Des Périers (*q.v.*), while it exiled and virtually killed Marot, also threatened Rabelais. It is certain that he passed nearly the whole of 1546 and part of 1547 at Metz in Lorraine as physician to the town at a salary of 120 livres, and John Sturm, the educational reformer, speaks of him in a contemporary letter (dated March 28, but no year given) as having been "cast out of France by the times"; he himself in another letter gives a doleful account of his pecuniary affairs and asks for assistance. On the death of Francis I on March 31, 1547, Du Bellay went to Rome and at some date

not recorded Rabelais joined him. He was certainly there before June 1548, and remained there until September 1549; he dates from Du Bellay's palace a little account of the festivals given at Rome (March 14, 1549) to celebrate the birth of the second son of Henry II and Catherine de Médicis. This account, the *Sciomachie* as it is called, is extant. In the same year a monk of Fontevault, Gabriel du Puits-Herbault, made in a book called *Theotimus* the first of the many attacks on Rabelais. It is, however, as vague as it is violent; and it does not seem to have had any effect. Rabelais had again made for himself protectors whom no clerical or Sorbonnist jealousy could touch. The *Sciomachie* was written for the cardinal of Guise, whose family was all-powerful at court, and Rabelais dedicated his next book (*Le Quart Livre*) to Odet de Châtillon, afterward cardinal. Thus Rabelais was able to return to France, and in January 1551 was presented to the livings of Meudon and Saint-Christophe du Jambet. There is very little ground for believing that the "curé of Meudon" ever officiated or resided there. He certainly held the living for less than two years, resigning it on Jan. 9, 1553, with his other benefice, and at the episcopal visitation of 1551 he was not present.

Some chapters of Book IV had been published in 1548, but the whole of it did not appear until 1552. The Sorbonne censured it and the *parlement* suspended the sale, taking advantage of the king's absence from Paris; the suspension was soon removed. Rabelais died, it is said, on April 9, 1553, in Paris. The legends of his deathbed utterances—"La farce est jouée," "Je vais chercher un grand peut-être," etc.—are entirely apocryphal.

Ten years after the publication of Book IV and nine after the supposed date of the author's death there appeared at Lyons 16 chapters entitled *L'île sonnante par maître François Rabelais* (1562); two years later the entire Book V was printed as such. In 1567 it took its place with the others and has ever since appeared with them, though from the beginning of the 17th century there have been disbelievers in its authenticity. It is possible, and indeed almost certain, that it was prepared from his papers by the hand of a Protestant, after the Massacre of Vassy (March 1, 1562).

(G. SA.; JE. PO.)

The Nature of the Work.—Rabelais' purpose was to entertain the cultivated reader at the expense of the follies and exaggerations of his times. If he points lessons, it is because his life has taught him something about the evils of comatose monasticism, the trickery of lawyers, the pig-headed persistence of litigants, and the ignorance of grasping physicians. He was a friar with unhappy memories of his monastery; his father had wasted his money on lengthy litigation with a neighbour over some trivial water rights; and he was himself earning his living by medicine in an age when the distinction between physician and quack was needle-fine. Though it is an entertainment, therefore, his book is also serious. Its principal narrative is devoted to a voyage of discovery which, though it parodies the travelers' tales current in Rabelais' day, has something of the imaginative intensity of Don Quixote's three expeditions. Like Cervantes, Rabelais begins lightheartedly. His travelers merely set out to discover whether Panurge will be cuckolded if he marries. A dozen oracles have already hinted at his inevitable fate, yet each time he has reasoned their verdict away; and the voyage has provided a number of more amusing incidents. Yet, like Quixote's, it is a fundamentally serious quest directed toward a true goal, the discovery of the secret of life, for "men are searchers and discoverers," as Rabelais tells us in his final chapter.

The oracle of the "*Dive Bouteille*" (sacred bottle), when it is spoken in the fifth book (to which Rabelais did not give final form), is delivered in an atmosphere of hocus-pocus. Yet its monosyllabic *Trink* is completely serious. Rabelais is not recommending intoxication with wine. Yet intoxication—with life, with learning, with the use and abuse of words—is the prevailing mood of the book. It is true that there are great scenes of drunkenness, as on the occasion of Gargantua's birth. But elsewhere Rabelais scolds the monks for their boozing, and there is no room in his model and secular abbey of Thélème for drunkenness, only for the conviviality of friendship and good living.

Rabelais himself provides the model of the intoxicated man,

the exuberant creator. Words fly to his head. His five books provide a cunning mosaic of scholarly, literary, and scientific parody. One finds it in its simplest form in the catalogue of the library of St. Victor, in the list of preposterous substantives or attributes in which Rabelais delights, and in the inquiry by means of Virgilian lots into the question of Panurge's eventual cuckoldom. But at other times the humour is more complicated, and works on several levels. Gargantua's campaign against King Picrochole (Book I), for instance, contains personal, historical, moral, and classical points closely interwoven. The battles are fought in Rabelais' home country, in which each hamlet is magnified into a fortified city. Moreover they refer also to the feud between Rabelais the elder and his neighbour. They also have historical connotations, however, and comment on Charles VIII's campaigns in Brittany and Charles V's imprisonment of Francis I after the Battle of Pavia. They could even be read as propaganda against war, or at least in favour of the more humane conduct of hostilities. On yet another level, Rabelais' account of this imaginary warfare can be taken as mockery of the classical historians. Gargantua's speech to his defeated enemy (Book I chapter 50) echoes one put into the mouth of the emperor Trajan by Pliny the Younger.

Rabelais' readers no doubt missed many of the references that have been tracked down by scholars. They no doubt saw that he was laughing at Livy or Cicero or Pliny, but could not have guessed at the parallel between these battles and a local quarrel in his boyhood. But Rabelais was not a consequent or self-conscious writer; he made his book out of the disorderly contents of his mind. It is ill-constructed; the same thoughts are repeated in *Gargantua* that he had already set down in *Pantagruel*. The nature of an ideal education, for example, is examined in both books. Moreover, the main action of the story, which arises from the question of Panurge's intended marriage, only begins in the third book. The first, *Gargantua*, throws up the enormous contradiction which has made the interpretation of Rabelais' own standpoint almost impossible. On the one hand we have the rumbustious festivities that celebrate the giant's peculiarly miraculous birth and the "Rabelaisian" account of his childish habits; and on the other a plea for an enlightened education, like that subsequently devised for Montaigne by his father. Again, the brutal slaughter of the Picrocholine wars, in which Rabelais obviously delights and in which the most jovially barbaric slaughterer is the beloved Friar John of the Hashes, is followed by the utopian description of Thélème, the Renaissance ideal of a civilized community. *Pantagruel* follows the same pattern with variations, introducing Panurge but omitting Friar John, and putting Pantagruel in the place of his father. In fact the characters are not strongly individualized. They exist only in what they say, being so many voices through whom the author speaks. Panurge, for instance, has no consistent nature. A resourceful and intelligent poor scholar in *Pantagruel*, he becomes a credulous buffoon in the third book and an arrant coward when he lies blubbing during the storm in the fourth. So little did Rabelais care for character that he lifted four of Pantagruel's companions from the poem *Baldus* by Teofilo Folengo (*q.v.*), who wrote under the name of Merlin Cocai. Indeed, Panurge himself, in his later existence, seems to be modeled on Cocai's buffoon Cingar.

The third, fourth, and fifth books pursue the story of the inquiry and voyage, borrowing from time to time from Lucian, the classical writer to whom Rabelais is most akin. But at least in the third and fourth, Rabelais' invention is at its height. The early books contain incidents close in feeling to the medieval *fabliaux* (*q.v.*); the later are rich in a new, learned humour. Rabelais can be compared with James Joyce as a writer molded by one tradition, the medieval-Catholic, whose sympathies are to a greater extent with another, the Renaissance or classical. Yet when he writes in praise of the new ideal, in the chapters on education, on the foundation of Thélème, on the mysterious herb Pantagruelion—which appears to be hemp and to symbolize the virtues of hard work—or in praise of drinking from the sacred bottle—of learning or enlightenment—he easily becomes sententious. His head is for the new learning; his flesh and heart belong to the old. It is in his absurd, earthy, and exuberant inventions,

which are medieval in spirit even when they mock at medieval acceptances, that Rabelais is a great, entertaining, and worldly-wise writer. Here too he is like Joyce, and the comparison goes further. Like Joyce, Rabelais is a master of language. He uses and misuses words, making them mean what he will. To define the spirit of Pantagruelism is impossible. To recognize it and enjoy it, one has only to take a swig at the sacred bottle of his book.

(Jo. M. C.)

BIBLIOGRAPHY.—*Editions, etc.*: The first complete edition of Rabelais was published by Jean Martin (Lyons, 1567). By 1600 about 60 editions had been published (see P. P. Plan, *Bibliographie rabelaisienne, 1532–1711, 1904*). The first important critical edition was that of Le Duchat (Amsterdam, 1711). Elloi Johanneau published an elaborate edition in 9 vol. (1823–26). Later editions include those by Charles Marty-Laveaux, 6 vol. (1868–1903); Abel Lefranc, 6 vol. (1912–55); Jean Plattard, 5 vol. (1929); and J. Boulenger, 1 vol. (Pléiade, 1959); and P. Jourda, 2 vol. (1962). There have been many commentaries on Rabelais, beginning with that of Jean Bernier in 1697. A complete and exhaustive bibliography has been supplied by A. Cioranescu, *Bibliographie de la littérature française du XVI^e siècle* (1959), no. 17,934–18,789.

Translations: Sir Thomas Urquhart translated the first two books of Rabelais into English in 1653; his work reproduced the spirit of the original with remarkable felicity and was recognized by many as a masterpiece of translation. In 1693 Pierre Motteux republished Urquhart with a long commentary and added the third book which Urquhart had not completed. Later Motteux translated the last two books. W. F. Smith made a new translation of the five books and minor writings in 1893 and a second edition of this appeared in 1934. Other English translations are those by S. Putnam, 3 vol. (1928); J. Le Clercq, 5 vol. (1942); and J. M. Cohen (1955).

(JE. Po.)

RABI, ISIDOR ISAAC (1898–), U.S. physicist, invented in 1937 the atomic and molecular beam magnetic resonance method for observing spectra in the radio-frequency range. Subsequent development of several spectroscopic methods over a wide frequency range depended greatly on Rabi's pioneering work, for which he was awarded the Nobel Prize in 1944. The importance of the work lies in the fact that a number of fixed mechanical and magnetic properties and the shape of a nucleus in an atom or molecule may be deduced from the observations of radio-frequency spectroscopy (*q.v.*). The observations also yield detailed information about the structure of atoms and molecules.

Born in Rymanow, Aus., on July 29, 1898, and raised in the United States. Rabi received a Ph.D. degree from Columbia University in 1927, joined its faculty in 1929 and became professor of physics in 1937. After he spent the year 1928 in Germany in the laboratory of Otto Stern, who had done important work with atomic beams, Rabi's continuing work in this field brought refinements in experimental technique and increasing insights into atomic phenomena. After 1940 he was active in research administration, and dealt with the relationships of scientific inquiry and its technological consequences to national and international affairs. From 1940 to 1945 he was associate director of the Radiation Laboratory of the Massachusetts Institute of Technology, Cambridge, Mass., for the development of microwave radar. After World War II Rabi served on various government scientific committees, including the general advisory committee of the U.S. Atomic Energy Commission. He was also a U.S. representative to

UNESCO and was instrumental in arranging the 1955 Geneva conference on the peaceful uses of atomic energy, of which he was a vice president. In 1962 Rabi was appointed to the general advisory committee for the U.S. Arms Control and Disarmament Agency.

(P. Кн.)

RABIES (HYDROPHOBIA) is an acute, ordinarily fatal, infectious disease of the central nervous system caused by a virus and is, as a rule, propagated in domestic dogs and wild carnivorous animals such as the wolf, jackal, coyote, fox, mongoose and skunk. Rabies is propagated by vampire bats and insectivorous bats in some regions. Man and all warm-blooded animals are susceptible to infection with rabies.

History.—Rabies has been known in Europe and Asia since ancient times. The period of summer reckoned by the heliacal rising of the dog star, Sirius, has since antiquity been referred to as "dog days," when dogs are supposed to be especially liable to spells of madness. The people of ancient Egypt, Greece and Rome ascribed rabies to evil spirits because ordinarily docile and friendly animals developing this disease became suddenly vicious and aggressive without evident cause and, after a period of maniacal behaviour, developed paralysis and died. Aristotle (d. 322 B.C.) recognized the relationship of hydrophobia in man to rabies in animals and recommended cauterization of wounds produced by rabid dogs.

The transmission of rabies from a rabid dog to a normal dog by the inoculation of saliva was accomplished by Zinke (1804), by Grüner and by Salm-Reifferscheidt (1813). These experimental studies showed that the disease was infectious, and on the basis of this evidence it was assumed that destruction of stray ownerless dogs and quarantine of other domestic dogs would eliminate the disease. Sanitary measures including these provisions were adopted in Norway, Sweden and Denmark, and by 1826 these countries were free from rabies and remained so. Rabies was eliminated from some urban centres in continental Europe during the 19th century, but after a few years these areas frequently became reinfected, since rabies was established among the wild animals.

Nature of the Disease.—The disease often begins with such symptoms of excitation of the central nervous system as irritability and viciousness. During the early stages of the disease a rabid animal is most dangerous because it appears to be healthy and may seem friendly but will bite at the slightest provocation. Wild animals which appear to be tame and approach man or human habitation in daytime should be suspected of having rabies. The virus is often present in the salivary glands of rabid animals and is excreted in the saliva, so that the bite of the infected animal introduces the virus into a fresh wound. Under favourable conditions, the virus becomes established in the central nervous system by propagation along nerve tissue from the wound to the brain. When infection occurs, the disease develops most often between four and six weeks after exposure, but the incubation period may vary from ten days to at least eight months.

Bat Rabies.—A variety of rabies propagated by the vampire bat, *Desmodus rotundus murinus* Wagner, is known as paralytic rabies, paresian rabies, *mal de caderas* and *derriengue*. Although the disease symptoms produced by this virus differ from those of rabies contracted from dog bite, they are varieties of the same disease. One vaccine will protect against all types of rabies. In the vampire bat the rabies infection sometimes is limited to the salivary glands so that the animal can transmit rabies by bite for a period of several months without exhibiting symptoms of illness. This animal lives on blood alone and feeds by biting and lapping up the blood after inflicting a craterlike wound with its sharp incisor teeth. Therefore it does not need to become vicious in order to transmit rabies. Vampire bats are found only in Mexico, Central America and South America. The occurrence of epizootics of cattle rabies in Brazil, Trinidad and Mexico, in regions where dog rabies was rare or unknown, stimulated research on rabies during the period 1931-44 which resulted in the discovery that rabies exists as an enzootic disease of vampire bats in these countries. Rabies is found also in fruit-eating and insect-eating bats. Bats found flying in daytime or which try to attack and bite are

likely to be infected with rabies.

Dog Rabies.—Dog rabies is commonly classified as furious rabies or dumb rabies, depending on the signs shown by the animal. In the former type the excitation phase is prolonged, while in the latter the paralytic phase is present from the beginning or develops early. Most infected dogs show some manifestations of each type, that is, a short excitation phase characterized by restlessness, nervousness, irritability and viciousness, followed by depression and paralysis. Sudden death from rabies, without recognizable signs of illness, is not uncommon. Dogs that develop the predominantly excited type of rabies invariably die of the infection, usually within three to five days after the onset of symptoms. Dogs developing the paralytic type of rabies without any evidence of excitation or viciousness may in rare instances recover from the infection. The symptom of hydrophobia or fear of water does not occur in dogs, but difficulty in swallowing is a common symptom of dog rabies. The paralysis of the muscles of phonation in rabid dogs often produces a characteristic change in the bark. There is no characteristic seasonal incidence of dog rabies.

Hydrophobia or Human Rabies.—Rabies in man is similar to the disease in animals. The excitation phase may continue until death occurs during a convulsive seizure. More often, symptoms of depression of the central nervous system develop before death. The hydrophobia symptom consists of repeated episodes of painful contraction of the muscles of the throat on attempting to swallow. This symptom may be elicited by the sight of water because of the association of water with the act of swallowing, hence the fear of water or hydrophobia. Rabies in man is uniformly fatal when associated with excitation of the nervous system and the hydrophobia symptom. Death ordinarily occurs within three to five days after the onset of symptoms. Abnormal sensations about the site of exposure are a common early symptom of rabies. Sometimes the disease is characterized by paralysis without any evidence of excitation of the nervous system. In such cases the disease may be prolonged to a week or more and recovery does occur on rare occasions. Human rabies contracted from the bite of vampire bats is uniformly of the paralytic type and the hydrophobia symptom does not occur. Rabies virus is often present in the saliva in human rabies and saliva specimens are examined for rabies virus by the mouse inoculation test.

Diagnosis.—Inclusion bodies, first described by A. Negri (1903), are found in the nerve cells of the brain of animals that die of rabies. They are not always present but a prompt diagnosis of rabies can be made in about 90% of the cases of furious rabies in dogs by demonstration of Negri bodies in the brain tissue after the animal dies. Negri bodies are found more frequently in those animals that show symptoms of viciousness for several days before they die of rabies. They are a specific reaction product and not a visible form or conglomerate of virus particles. Negri bodies are not found in the brains of animals infected with fixed varieties of rabies virus (see below).

The mouse test for rabies virus consists of intracerebral inoculation of mice with aqueous extracts prepared from brain tissue, salivary gland tissue or diluted saliva from cases of suspected rabies. Mice are uniformly susceptible to infection with rabies virus when thus inoculated and ordinarily sicken and die about one week after inoculation. The diagnosis of rabies is confirmed by demonstration of Negri bodies in the brain tissue.

Treatment.—**Investigation by Pasteur.**—The discovery by Louis Pasteur (1881) that the infective agent of rabies could be recovered in a relatively pure state from the brain of an animal that died of the disease opened the way for an extensive study of rabies. Since the infective agent as obtained from brains of rabid animals could not be identified by microscopic examination and could not be cultivated in nutrient mediums used for the growth of ordinary bacteria, it was called virus, from the Latin word for poison. The ultramicroscopic nature of some disease-producing organisms was first postulated by Pasteur. He was also the first to modify the pathogenicity of a virus for its natural host by serial intracerebral passage in another host. In an attempt to develop a variety of rabies virus which could be used safely for

vaccination, he passaged the virus of rabies intracerebrally in rabbits. This resulted in the development of an infection characterized by a short, fixed incubation period; this modified virus was called fixed, to distinguish it from the natural, or so-called street virus. After 100 passages in rabbits, the fixed virus had little capacity to infect dogs when given by subcutaneous inoculation. By means of a series of ten daily subcutaneous injections of fixed virus, graded from no infectivity to maximum infectivity by drying infected rabbit spinal cord tissue at room temperature for various time periods, dogs were made resistant to experimental infection with the natural street virus. During 1885, a peasant boy who had been severely bitten by a rabid dog was taken to Pasteur, and, in view of the serious nature of the exposure and the plea that something be done, the boy was vaccinated in a manner similar to that used for immunization of dogs, the theory being that, if dogs could be immunized in a two-week period so that they would resist infection with the natural virus, the long incubation period of rabies in human beings would allow the development of a high grade of immunity before the potential onset of the disease. The treatment appeared to be without ill effect and the boy remained well. This became known and other persons were taken to Pasteur for treatment; soon the vaccine treatment for rabies was adopted as a routine procedure in medical centres throughout the world. The mortality from rabies was reduced from about 9% for all types of bites by rabid dogs to less than 0.5%. In rare instances the vaccine treatment will not prevent the onset of rabies, because the virus produces the disease before an adequate immunity is achieved by vaccination. (See also PASTEUR, LOUIS.)

Vaccine Treatment (Active Immunization).—There have been many modifications of the Pasteur method of vaccination with live fixed virus vaccine. C. Fermi (1908) was the first to use chemical treatment—with phenol—of the fixed virus in the preparation of the vaccine. Later D. Semple (1919) showed that by incubation of the phenol-treated fixed virus at 37° C. it could be killed and still retain its capacity to immunize. A variety of chemical and physical methods have been used for inactivating fixed virus for the preparation of rabies vaccine. The commonly employed vaccines are the live fixed virus (Pasteur strain), the killed-virus vaccines of the Semple type and the U.V. (ultraviolet light treated) type. The vaccine treatment consists of 7 or 14 daily injections, depending on the severity of the exposure to rabies.

Serum Treatment (Passive Immunization).—V. Babès and Lepp (1889) introduced the serum treatment whereby animals are immunized with fixed rabies virus and the blood serum of these animals is injected into exposed persons to give them temporary immunity to rabies. This treatment is most effective if given within 24 hours after exposure. It has little value, if any, when given three or more days after exposure to rabies. A combination of serum and vaccine treatment is given in cases of severe exposure to rabies. Immediate treatment of animal bite wounds by cleansing with soap and water is important because much, if not all, of the virus can be removed thus. Chemical treatment is to be avoided before the wound is seen by a physician.

Control of Dog Rabies.—Dog rabies can be eliminated by enforcement of quarantine regulations for dogs, except in those regions where rabies is present in wild animals. Rabies has been kept out of Australia, Great Britain, Denmark, Norway, Sweden and the Hawaiian Islands by enforcement of quarantine regulations for imported dogs. The fact that dogs have developed rabies while under quarantine in these countries, and the development of rabies in dogs eight months after their arrival in Great Britain, makes it certain that the virus can remain latent in an exposed dog for at least this period of time. The eradication of rabies from Great Britain (1903) was accomplished with great difficulty and with much opposition from the dog-owning public because the quarantine regulations for dogs had to be maintained for several years before the disease disappeared. The vaccination of dogs, when combined with the collection of ownerless dogs, will eliminate dog rabies. The single-dose vaccination for dogs with Semple-type vaccine combines in one dose the amount of killed fixed virus ordinarily given in a complete course of vaccine treatment for

persons bitten by rabid animals. The avianized live virus vaccine (Flury strain) is a fixed virus modified by serial intracerebral passage in one-day-old chickens and by prolonged cultivation in chicken embryos. This live virus vaccine is used for immunization of dogs and a single injection of the vaccine will produce good immunity for at least three years following vaccination.

RACAN, HONORAT DE BUEIL, SEIGNEUR DE (1589-1670), French poet, and one of the earliest members (1635) of the Académie Française. His celebrated *Stances sur la Retraite* (c. 1618) are as much a witness to his good-natured indolence as to the poetic discipline of his master, François de Malherbe (q.v.), whose life he wrote. He was born at Champmarin (on the borders of Maine and Anjou) on Feb. 5, 1589, became a page at the court of Henry IV, served in the army, and in 1639 retired to his country seat in Touraine. His best-known work is a pastoral drama, *Les Bergeries*, performed at the Hôtel de Bourgogne in about 1620 and published in 1625. (See PASTORAL.)

His other poems are mainly bucolic and religious. His verse paraphrases of the Psalms, to which he devoted his retirement, are marked by sincerity and more feeling for the beauties of the original than was usual at the time. He died in Paris on Jan. 21, 1670.

SA.)

RACCOON, a common name for several carnivorous mammals of the family Procyonidae. The typical North American raccoon, or coon (*Procyon lotor*), with a stout body, short legs, bushy tail, and small, erect ears, measures 2½ to 3 ft. long, including the 10-in. tail, and weighs about 20 lb. (however, a very large male may weigh 50 lb.). The fur is shaggy and coarse, iron gray to blackish with brown overtones; the face displays a conspicuous black mask; the tail is ringed with five to seven black bands. The feet are small; the forefeet especially resemble delicate, slender human hands, and are used almost as such.

Raccoons prefer the vicinity of water in woods but are not restricted thereto. They eat a variety of arthropods, rodents, birds and their eggs, frogs, berries, fruit, and other vegetative materials. Their fondness for eggs, nestlings, corn, and melons makes them a nuisance in local areas. If water is available, they "wash" their food even though they may have just captured it from the water by probing beneath underwater rocks with their sensitive "hands." They climb trees readily, principally for refuge rather than for food. The preferred den site is a large hollow branch of a tree, where the three to six young are born after

WILLIS PETERSON

RACCOON (PROCYON LOTOR)

a gestation of 63 days. Raccoons are selectively polygamous, breeding in midwinter in cooler climates and around the year in warm climates. The female is highly solicitous of her young and cares for them for about a year, even though the young begin hunting food and are weaned when two months old.

Raccoons are seldom abroad in daylight. In very cold weather they sleep for extended periods but do not hibernate in the sense of becoming torpid. They are hunted and trapped extensively for their fur and tasty flesh. Most commonly they are hunted at night by trained hounds; when hard pressed they "tree" and can be shot easily. A much-hunted old raccoon becomes as wily and elusive as the cleverest fox.

Raccoons are inquisitive, methodical, and intelligent, and when young make agreeable pets; older animals tend to become irascible. Full-grown raccoons are preyed upon by few animals. When cornered they are savage fighters, ripping and slashing with claws and teeth; few dogs can successfully attack an adult. Especially in water, where he is very much at home, a raccoon often will drown his adversary. Raccoons adapt to man's presence exceptionally well, and are not uncommon even close to metropolitan areas, provided food and den sites are available. Although raccoons thrive in captivity, raising them is not profitable because of their large appetites and the low value of their pelts.

P. lotor and its closely related species occur from northern Alberta, over the United States, excluding the High Plains and Great Basin regions, and southward into South America. One species (*P. maynardi*) is known only from the Bahama Islands, and two other species from Barbados and Guadeloupe islands in the Lesser Antilles. A related species, the large crab-eating raccoon (*P. cancrivorus*), inhabits much of South America as far south as northern Argentina. See also CARNIVORE. (K. R. KN.)

RACE RELATIONS: see INTERRACIAL RELATIONS; ACCULTURATION; APARTHEID; CAPE COLOURED; CIVIL LIBERTIES; MARRIAGE, LAW OF: *United States: Impediments to Marriage*; MIGRATION; NATIVISTIC MOVEMENTS; NEGRO, AMERICAN; PSYCHOLOGY, SOCIAL; *Simple Group Effects*; SEGREGATION, RACIAL; SOUTH, THE.

RACES OF MANKIND. Race as a biological concept in man and other animals refers to the taxonomic (classificatory) unit immediately below the species. Biologically, a race is a population or a group of populations distinct by virtue of genetic isolation and natural selection; in these terms a race is neither an artificial construct, a collection of individuals arbitrarily selected from a population, nor a religious grouping, linguistic division, or nationality. In man, in which only one species (*Homo sapiens*) survives, race serves as a major basis for distinguishing one person from another. Investigation in anthropology is concerned with the origin (phylogeny) of races, their classification and relationships, and the documentation of evolutionary mechanisms involved in racial differentiation.

Satisfactory explanations for the many differences among races were difficult to formulate until after the advent of evolutionary genetics (see MAN, EVOLUTION OF). Tradition favoured an oversimplified phylogeny, a three-race theory, and admixture to account for all living races of mankind. Modern research clearly documents the role of local environments in bringing about genetic differences among races.

Geographical, Local, and Micro-Races.—The term race alone is, however, inadequate to describe the larger and smaller natural units that can be distinguished. In Africa south of the Sahara, for example, all native peoples are obviously related and quite distinct from the populations of Europe or Asia; nevertheless, within Africa there are numerous local populations such as the Bushmen and Hottentots, or the pygmies of the rain forest, that are clearly distinct. The peoples of West Africa, in Ghana and Ivory Coast, are demonstrably different from those of East Africa and the Sudan. Such larger geographical groupings and smaller local groupings are more easily described by reference to geographical races (the larger group) and local races (the smaller group).

There are relatively few geographical races, and these coincide fairly well with the major continents or great island chains. In all, nine geographical races may be defined as follows: American Indian, Polynesian, Micronesian, Melanesian-Papuan, Australian, Asian, Indian, European, and African. This system of geographical races accounts for the vast majority of the world's population, excluding only a few groupings, such as the Ainu of northern Japan, and some of the aboriginal tribes of Formosa (Taiwan) and southwest China. It is a convenient system, referring in general to collections of populations that have long been isolated from each other and that have developed many distinctive features.

Nevertheless, geographical races as units do not lend themselves to direct investigation. It would be a formidable task

to study Africans, for instance, or American Indians, or Australians as independent groupings. Actual studies of races involve the far smaller, often clearly delimited local races, examples of which include the Lapps of Scandinavia, the Ituri forest pygmies of Africa, or the Alacaluf of Patagonia. There are in fact hundreds of local races, some of them relatively isolated for thousands of years (as the Andamanese) and others of recent development (as the Neo-Hawaiian and American Negro). Most commonly, it is such local races as these that are studied.

In more densely populated places, however, such as Western Europe, Southeast Asia, or West Africa, it is difficult to find local races as neatly delimited as Lapps, Ainu, Apache, or Bushmen. Nevertheless, genetic makeup differs from locality to locality, as can be documented by blood-group frequencies, taste acuity, palm-print patterns, and frequencies of many other genetically determined traits. The term micro-race conveniently describes such smaller divisions, which are most conveniently studied by physical anthropologists and geneticists.

Race Differences.—Races differ considerably in size and shape, in pigmentation and blood-group frequencies, in dress, and in behaviour. Leaving out such obviously learned differences as costume or gesture, and differences due to the way of life or availability of food, characteristics of most value to the scientific study of race are hereditary (see GENETICS OF POPULATIONS).

Such genetic differences include size, shape, and cusp number

TABLE I.—Some Morphological Differences
Among Races and Populations

Trait	Comments
Bone density	Higher in American Negroes than in American whites
Suture bones on the back of the skull	Common in many American Indian populations and in Asians
Shovel-shaped incisors	Especially common in American Indians of the Southwest
Agenesis of third molars	Common in American Indians, rare in Africans
"Peppercorn" or spiral tuft hair form	Limited to Africa, south of the Sahara, especially well developed in Bushmen
Internal or Mongoloid eyefold	Limited to Asia, the Pacific Islands, and the Americas
Male pattern baldness	Especially common in Europeans, rare in American Indians and many Asians

of teeth; proportions and even densities of the various bones; and configurations of the skull and face. They include the form and abundance of head and body hair, the tendency toward male pattern baldness, and the number of sweat and sebaceous glands. Racial differences are obvious in palm prints and fingerprints; in the form of the eyelids, eyebrows, and nasal tip; in the thickness of the lips; and in the amount of pigmentation of the gums. The tendency to form raised scars (keloids), the ability to fold the tongue and to taste phenylthiocarbamide (PTC) and thiouracil also vary with race. (See GENETICS; GENETICS, HUMAN.) Racial differences also exist in the frequencies of the various blood groups, in the haptoglobins, in the abnormal hemoglobins, in sensitivity to numerous antimalarial drugs, and in resistance to various infectious and parasitic diseases, especially malaria.

However, such racial differences are rarely absolute. While many American Indians exhibit shovel-shaped incisors, not all of them do. It is the relative frequency of the B blood type that distinguishes Asians from Europeans; and the same is true of other blood groups, such as Kell, Kidd, or Lutheran. Moreover, races do not differ to the same extent in all trait frequencies or gene frequencies. Asians are markedly different from Europeans in the frequency of the Diego-positive blood type but not in the MN frequencies. American Indians and Australian aborigines are vastly different in MN frequencies but similarly low in the frequency of blood type B. (See BLOOD; Individuality of Human Blood; BLOOD GROUPS.)

Furthermore, contiguous races may be quite unlike in the frequency of a particular hereditary trait. American Eskimos differ from both American Indians and Asians in the frequency of the Diego-positive blood type and in the proportion of PTC taste-blind individuals, though resembling both Asians and American Indians in many other respects.

Thus, while races differ from each other in a great many gene-

determined traits, these differences are best expressed as trait, or gene, frequencies. A major racial difference in one respect may be associated with a minor difference in another. And, while geographically remote races, because of long isolation from each other, tend to differ most widely, they may be closer to one another in particular respects than they are to contiguous local races.

Blood Group Differences.—From data on blood groups that have been accumulated since 1900, it is now possible to generalize about many racial differences. Blood group B, for example, is virtually absent from the aboriginal peoples of the Americas and Australia and is found in about 12% of Europeans and in about 25% of Africans and Asian Indians. In some parts of Asia, however, B may be found in as much as 40% of the population. Furthermore, while blood type A is found in all geographical races, the A₂ subtype is uniquely European.

The Rh-negative blood type is peculiarly European. Approximately 15% of Europeans are Rh-negative (the frequency is far higher in the Basques), but Rh-negative individuals are extremely rare among Asians, Africans, and American Indians. In Africa, however, the Rh₀ subtype is especially common. In the MN series, M and N are equally common over most of the world; American Indians and Australians are extremes, being largely M and N respectively.

Differences among local races are especially apparent in the Diego system. Commonly, American Indians and Asians are Diego-positive. However, in some American Indian groups the frequency of Diego-positive individuals is near zero, especially among the northern tribes, and in fact among those geographically nearest Asia.

Racial differences also exist in the frequencies of the Kell, Kidd, Lutheran, and Duffy blood group systems; e.g., a vast majority of Indians and American Indians and 65% of Europeans are Duffy-positive, compared with less than 10% in Africa.

Such differences, as with the MN system, make it clear that a simple picture of three "original" races fails to account for the distribution of blood groups in the world. The fact that each blood group system has its own unique distribution indicates the paramount importance of local environmental factors in mediating racial differences.

Other Biochemical Differences.—A particularly well-known biochemical difference among races is the tendency to excrete β -amino isobutyric acid (BAIB). European and African adults rarely excrete BAIB, but it is commonly observed among Micronesians, Asians, and American Indians. Among the hemoglobin-fixing haptoglobins, the haptoglobin type Hp¹ is commoner in Europeans and the Hp² type is commoner in Africans. Racial differ-

ences also exist in the frequency of the abnormal hemoglobins C, D, E, and S, and in blood glutathione instability.

ences also exist in the frequency of the abnormal hemoglobins C, D, E, and S, and in blood glutathione instability.

Race and Disease.—Since races are natural units, reproductively isolated and adapted to particular local environments, it is not surprising that there are racial differences in the frequency of various genetically determined diseases. A record example is kuru, a hereditary, progressive neurological disorder so far known only in the Fore peoples of eastern New Guinea. In the Mediterranean area is found a hereditary blood disorder, thalassemia, with a minor and a major form. A similar but genetically independent condition is the so-called sickling trait and the severe sickle-cell anemia that is found in much of Africa south of the Sahara and in a smaller proportion of American Negroes. Ab-

normal hemoglobins characteristic of thalassemia and sickle-cell anemia are also found in a broad belt stretching to India and Indonesia. (See also ANEMIA.) Some persons of Mediterranean origin and many from Africa have a hereditary red blood cell glutathione instability, which renders them sensitive to certain substances, among them the fava or broad bean (*Vicia faba*), many antimalarial drugs, and some sulfa drugs. Affected persons may suffer red blood cell destruction by eating a plate of fava beans, or even by walking through a field of beans in flower. These beans were a prohibited food in ancient Egypt, apparently in recognition of their potential threat to susceptible persons.

Yet thalassemia, sickling trait, and hereditary drug sensitivities are not without their compensations. Persons with thalassemia minor or with the sickle-cell trait are to some extent protected against malaria, as, apparently, are drug-sensitive persons and those who suffer from favism. The striking coincidence of the distributions of abnormal hemoglobins, glutathione instability, and malaria is interpreted as indicating the selection pressure that malaria exerts in favour of thalassemia minor and sickle-cell trait and the sensitivity to certain drugs.

Race and Climate.—The fact that different races inhabit climatic zones ranging from Arctic to tropical suggests some degree of genetic adaptation, and there is indeed indirect evidence of climatic adaptations. The people of Tierra del Fuego and some Australian aborigines sleep almost nude at near-freezing temperatures. American Negro troops experienced more cold injuries than did white during the Korean War, and there is evidence that they withstand humid heat better. Texans of European ancestry tend to develop skin cancer in outdoor occupations. Eskimos retain the finer motor skills even when their hands are exposed to severe cold. Experimental studies bear out some of these suggestions: Eskimo peripheral skin temperatures remain higher than normal in the cold; Negro-white differences in sweating capacity and heat tolerance have been confirmed; Australian aborigines endure moderate night cold because their skin temperatures and metabolic rates are lowered.

Such differences, however, point to the importance of local races and local environmental factors. Australians of the tropical zone are not cold-adapted; northern Europeans appear to adapt to cold more easily than southern Europeans do. While the Congolese may be adapted genetically to humid heat, Bushmen seem to be better fitted for drier and cooler conditions.

Origin of Races.—Individual races arise from evolutionary mechanisms working on isolated populations. A race long resident in a particular environment encompasses a series of genetic adaptations to that environment. By whittling away less adaptive traits and favouring those more adaptive under the particular circumstances, an optimum genotype results: that is, a genetic constitution best fitted to the circumstances.

Numerous evolutionary mechanisms are involved in race formation. In small populations genetic drift (random changes in gene frequencies) is at work. Race mixture inevitably results in new genotypic combinations, some deleterious, others superior to either parental group. Mutations add new genes to be acted upon by natural selection. Inevitably and always there is the screening effect of environment and of natural selection—the major evolutionary mechanism responsible for the differences among races (see SELECTION).

All human races, geographical and local, past and present, seem to derive from a relatively small group of early *sapiens* hominids originating perhaps half a million years ago. As this small but variable group increased in number, and segments moved into different climatic and geographical zones, genetic isolation and differential selection apparently led to the formation of numerous race populations. These, in turn, probably gave rise to further races down to the present. With this continual change, it is obvious that no contemporary population resembles the original *sapiens* progenitors of mankind, nor can it be said that particular races are "purer" or less changed than others. Likewise, it is impossible to guess, from examination of living races, what the pigmentation, facial features, or blood groups of the earliest races of man might have been.

TABLE II.—Biochemical Differences Among Races and Populations

Trait	Frequencies in different populations
Haptoglobins	Hp ¹ in over 60% of Africans, over 40% of Europeans, and under 20% of Asian Indians
BAIB excretion	Extremely rare in adult Europeans, common in American Indians and Asians, and absent in Eskimos
Taste "blindness" to PTC, thiouracil	Under 5% in most American Indians and Africans, 20-30% in Europeans, and over 40% in western India
Drug sensitivity (glucose 6-phosphate dehydrogenase deficiency)	Low in northern Europeans, up to 20% in Mediterranean, up to 30% in Africa, and up to 15% in lowland South American Indians

Population Size of Individual Races.—Populations of individual races vary from less than a hundred people for some, to thousands for others, to hundreds of millions for yet others. The number of Bushmen is minuscule compared to the southeast Asian local race, and the size of the American Negro population is 10,000 times that of the Ainu.

The populations of a few geographical races, as the aboriginal Australians, have decreased markedly in the last few centuries. Some American Indian groups have gone to extinction; on the island of Umnak, in the Aleutians, the number of Aleuts has decreased from 25,000 to less than 100. Other American Indian groups have increased in size, and certain European and Asian populations have multiplied fourfold in less than a century. In mid-19th century the increase in numbers of the Bantu-speaking peoples set them on a path of expansion and conquest to the southern tip of Africa.

Five thousand years ago there were probably more Australian aborigines than northern Europeans. The population of Italy 2,000 years ago exceeded that of England, Ireland, Germany, and the Low Countries. Clearly, the modern size of particular racial populations is no indication of their past magnitude or of their future numbers.

Generally speaking, races that developed sedentary agriculture, with its greater assurance of food supply, far outstripped races dependent upon hunting and gathering. Increased numbers led to security and further population expansion, until balanced by disease attrition. Sanitation, public health, and regular medical care (plus organized attention to poverty) further led to population expansion in the technologically and socially most advanced races. With better medical care and food supply, the relative sizes of different races and populations are again changing. Antibiotics, infant care programs, and improved nutrition have, in a short span of years, as much influence on the relative sizes of races as all the technological advances since the introduction of agriculture.

Future of Races.—In the history of a species, any race is transitory, forming, expanding, then dying out or being absorbed by other races. Since the earliest man there have been thousands of different races, some now known only as fossils, others from historical records, and still others so recently extinct that photographs and plaster masks of the last survivors are available. Some local races, like the Ainu, seem doomed to extinction within the next century, while many American Indian local races are being incorporated into the larger community.

As populations increase and spread, the smaller local races lose separate identity, though leaving their traces in characteristic local differences in gene frequencies. Admixture, long an important race-forming mechanism, increases as distances are nullified by rapid transportation; and the races of today will not continue, since they are contributing to new races in process of formation.

Moreover, individual races undergo continual change, even when isolated. Changing environments, including the disease and food environments, mean corresponding changes in the genetic makeup of race populations. As malaria ceases to be a major health problem, through insect control and antimalarial drugs, the abnormal hemoglobins will probably decrease in frequency until ultimately they will be as rare in Sardinia, about Lake Victoria, or in Indonesia as they now are in northern Europe. On the other hand, increasing medical care and control of metabolic diseases, leading to survival and perhaps reproduction of persons who formerly would have died young, will probably—in favoured populations—result in an increased gene frequency for such conditions.

There will continue to be human races, though not necessarily the same races known today. Even in isolated areas with an unbroken line of continuity, races of the future will not be identical with those of today. Local races are the units of evolutionary change. While such change may be minimized through isolation or maximized through admixture, there is no way known to prevent changes in the genetic makeup of individual races or in the total number of races.

RACHEL, MLE (ÉLISA FÉLIX) (1820–1858), a leading French classical tragedienne, was born at Mumpf, Switz., Feb. 28, 1820, the child of wandering peddlers. She sang on the streets of Lyons and Paris, where her acting ability was quickly discovered by Isidore Samson, who taught her all the technique he had learned from Talma. Rachel studied classical statuary for posture, practised vocal intonations and gestures, performed in many academy plays and at 17 made her debut at the Comédie Française as Camille in Corneille's *Horace*. Press and public acclaimed the new star, who, although thin and less than five feet tall, dominated the stage with her regal bearing, fiery glances and intense concentration.

Rachel was admired for her pantomime, the feverish excitement she brought to climactic scenes and the evil fascination of some of her characterizations. For 17 years she dictated the policy and program of the Comédie Française, bending its facilities and personnel to her will. Knowing that her genius and drawing power lay in classical plays, Rachel appeared in five by Corneille and seven by Racine, finding her greatest triumph in Racine's *Phèdre*. She was persuaded to join the popular romantic movement and appeared in plays by Hugo, Dumas père and De Musset, but of these only *Adrienne Lecouvreur* by Scribe and Legouvé was successfully received.

Rachel toured the provinces regularly and traveled to England, Austria, Russia, Italy, Germany and Belgium. Her United States trip in 1855 failed. Weakened from the constant struggle to maintain her artistic and social eminence, the strenuous touring and the vicissitudes of her notorious private life, Rachel died of tuberculosis on Jan. 3, 1858, and was buried at Père Lachaise in Paris.

RACHMANINOFF (RAKHMANINOV), SERGEI VASILIEVICH (1873–1943), Russian piano virtuoso and composer of piano and orchestral music and songs, was born at Onega in the Novgorod Government on April 1 (new style; March 20, old style), 1873. After a period of unsuccessful study at the St. Petersburg Conservatory (1882–85), he was sent to Moscow where he studied the piano with N. S. Zverev and Aleksandr Siloti and composition with A. S. Taneev and A. S. Arenski. He completed his

piano course in 1891 and his composition course the following year, winning a gold medal with his one-act opera *Aleko*. His First Piano Concerto dates from the same period. During the next two or three years he produced piano pieces and songs, an Elegiac Trio in memory of Tchaikovsky, an orchestral fantasia *The Rock*, and a symphony in D minor. The disastrous first and only performance of this First Symphony in St. Petersburg in March 1897 caused him to suffer a nervous collapse; he composed nothing more until 1900. From 1896 to 1898 his only musical occupations were as second conductor of the Mamontov Opera in Moscow and piano teacher in a girls' school. The popular Second Piano Concerto, in C minor, originally performed in 1900 without the first move-

THE BETTMANN ARCHIVE INC.

SERGEI RACHMANINOFF

ment (written in 1901), marked the resumption of Rachmaninoff's creative career. The concerto was soon followed by a cello sonata, the cantata *The Spring*, and more songs and piano pieces. A brief appointment as conductor of the Bolshoi Theatre in Moscow (1904-06) led to the composition of two short operas, *The Miserly Knight* and *Francesca da Rimini*.

From the autumn of 1906 to the summer of 1908 Rachmaninoff, with his family, lived in Dresden where he wrote four major works: the Second Symphony, in E minor (1907), a piano sonata in D minor (1907), the symphonic poem *The Isle of the Dead* (suggested by Böcklin's painting), and the Third Piano Concerto, in D minor (1909). This last was specially composed for a concert tour of the U.S. in the autumn of 1909, in which he appeared as composer, pianist, and conductor. (London had heard him in all three roles as early as 1899.) From 1910 to the Revolution Rachmaninoff again made his home in Moscow, appearing as conductor (e.g., of the Philharmonic concerts from 1911 to 1913) more often than as pianist. His compositions of that period include the *Liturgies of St. John Chrysostom* (1910), a choral symphony based on K. D. Balmont's translation of Poe's "The Bells" (1913), the Second Piano Sonata (1913), and the *Vesper Mass* (1915). At the end of 1917 Rachmaninoff left Russia for Scandinavia; in 1918 he went to the U.S. where he made his principal home for the rest of his life, though from 1931 to 1939 he spent his summers on a small estate on Lake Lucerne. After 1917 he devoted himself mainly to the career of piano virtuoso, appearing all over America and Europe (except Russia); but the Fourth Piano Concerto, in G minor, was written in 1927, and during the 1930s he found the leisure to compose *Variations on a Theme by Corelli* for piano (1932), *Rhapsody on a Theme by Paganini* for piano and orchestra (1934), the Third Symphony (1936), and three *Symphonic Dances* (first performed 1941). He died in Beverly Hills, Calif., on March 28, 1943.

Rachmaninoff was a superb pianist, and all his most characteristic works—the concertos and the Paganini rhapsody, the solo preludes and *Études-Tableaux* (1916-17), and the songs—are marked by rich, euphonious, and highly effective piano-writing. He had a modest but real gift for somewhat elegiac melody but no great creative range, and he never made any serious attempt to develop the harmonic idiom of his youth.

See J. Culshaw, *Sergei Rachmaninov* (1949); O. von Riesemann, *Rachmaninoff's Recollections* (1934); V. I. Seroff, *Rachmaninoff* (G. Ab.) (1950).

RACIBORZ (German RATIBOR), a town in the Opole *województwo* (province), Poland, lies on the upper Oder River near the Czechoslovak frontier. Pop. (1960) 32,000. It is a railway junction on the ancient trade route leading through the Moravian Gate into Czechoslovakia. The town's fine old buildings suffered damage in World War II. Raciborz has rail and road links with Wrocław, Cracow (Kraków), Katowice, and Ostrava, Czech. Its varied industries include the production of machinery, cosmetics, building materials, sugar, and tobacco; and there is flour milling and tanning. Mentioned in documents in the 12th century and chartered in 1235, Raciborz later became capital of an independent principality. In 1327 the principality became tributary to Bohemia. Both passed to the Habsburgs in the 16th century. In 1742 the town was seized by Prussia. At the partition of Upper Silesia in 1921, Raciborz was retained by the Germans. It returned to Poland in 1945, two-thirds of the town having been destroyed.

(T. K. W.)

RACINE, JEAN (1639-1699), the younger rival of Pierre Corneille (q.v.), and the master of French tragedy in the so-called classical period, was born in December 1639 at La Ferté-Milon, near Soissons. He was the first child of Jean Racine, a local official, and his wife, Jeanne Sconin, who died 13 months later in giving birth to a daughter. In 1642 his father married again, but died within 12 months. The paternal and maternal grandparents took charge of the son and daughter respectively; and when Jean's grandmother lost her husband—before Jean was 10—she withdrew to the convent of Port Royal des Champs, where her daughter Agnès had become postulant. Agnès took vows in 1648 and in 1689 became abbess.

Racine thus came early into the world of Port Royal (q.v.). He attended the famous "*Petites Écoles*" from the age of 10, probably at Paris and other centres as well as at the École des Granges, near the convent, and received instruction from Claude Lancelot, Pierre Nicole (q.v.), and Antoine Le Maître (see ARNAULD). He spent two years at the Collège de Beauvais, itself strongly marked by Jansenist doctrines; and then returned to Port Royal des Champs. He spent three further years of free study there, in touch with his masters, now dispersed by persecution, and with his kinsman, Nicolas Vitart, steward to the Jansenist and Cartesian duc de Luynes, whose château (Vaumurier) provided a refuge for Jansenist *solitaires*. In 1658 he went to Paris to study at the Collège d'Harcourt, also known for its links with Port Royal.

Racine, who had responded to the unique opportunities his Port Royal education provided, did not relish his philosophy classes at the Collège d'Harcourt. He had already written some Latin and French verses; and in Paris he developed his powers in French verse, and made literary and social contacts through his connection with the Vitarts, with whom he went to live, in their quarters at the Hôtel de Luynes, in 1659. He made several friends, among them the young literary abbé, François Le Vasseur, and Jean de La Fontaine (q.v.). Aided by Jean Chapelain and Charles Perault, in 1660 he published an ode, *La Nymphé de la Seine*, celebrating Louis XIV's marriage. He also composed a play—*Amasie*—with the encouragement of an actress of the Théâtre du Marais; but this was refused and has not survived. For another lost play, *Les Amours d'Ovide*, he had the advice of Mlle de Beauchâteau, a leading actress of the Hôtel de Bourgogne.

His close relations with the theatrical world were bound to cause concern to those closest to him at Port Royal; and in the autumn of 1661 he was sent to the cathedral town of Uzès in the south of France, where his maternal uncle was vicar-general. He was to take orders and obtain a benefice. He pursued side by side his theological studies and his literary occupations—reading, for example, Ariosto, extensively, and showing in his letters that he had no idea of renouncing the world nor his literary ambition. The benefice did not materialize and he returned to Paris some time between August 1662 and June 1663. A second ode, *Sur la Convalescence du Roi*, was printed in July, and a third, *La Renommée aux Muses*, in November 1663.

Dramatic Career.—Racine's dramatic ambitions had already been realized that summer when Molière (q.v.) put on his *La Thébaïde* at the Palais-Royal (June 20, 1664). The subject—which Racine knew from Euripides, Statius, Seneca, and from the *Antigone* (1638) by Jean de Rotrou (q.v.)—was that of the hostile twin sons of Oedipus who slay one another in single combat, one defending, the other attacking, his native Thebes. It is not a great play, but it has great moments and deserves attention for Racine's ruthless compression of the two plots presented so diffusely by Rotrou, and for the powerful expression he gives to the brothers' hatred.

His next tragedy, *Alexandre* (based on Quintus Curtius), also first played at the Palais-Royal (Dec. 4, 1665), reveals a greater desire to be in the fashion, and an advance in style. It shows Racine concerned to compete with Corneille on his own ground. Though it lacks the power of *La Thébaïde*, the magnanimity of Alexander and the nobility of Porus, the lofty sentiments of the rival princesses, are skilfully presented. When Racine published it (1666) he dedicated it to the king—the "Alexander" of that age. In the meantime, however, soon after its performance at the Palais-Royal, the tragedy was given privately by the actors of the Hôtel de Bourgogne, with Floridor (q.v.), the greatest tragic actor of his day, in the title role. It was transferred to their theatre on Dec. 18, 1665. Racine has often been criticized, no doubt justly, for a step which suggests ingratitude toward the great actor-manager-playwright who had given him his first chance, but it is recognized that Molière's company was considered inferior in tragedy to the older troupe. However much Racine may have concurred in Molière's satire of the "grand manner" in his *Critique de l'École des Femmes*, he disliked the diction of Molière's troupe, and he gave to the *Comédiens du Roy*, as the troupe of the Hôtel de Bourgogne were called, all his subsequent tragedies. He bu-

manized the "grand manner," and made of the rhymed Alexandrine an instrument capable of expressing the most subtle human nuances and the most violent passions, and of touching the heart.

Racine had "arrived" with *Alexandre*—but only in the face of "excommunications upon excommunications" from his aunt at Port Royal. One of these missives, probably of 1663, survives. She denounces his associations with people of the theatre and begs him to think of his soul. And now, after he had succeeded with *La Thébaine* and triumphed with *Alexandre*, there appeared in the press a series of *Lettres sur l'Hérésie imaginaire*, of which the last two, *Les Visionnaires*, were directed by Racine's old master, Nicole, against Jean Desmarets de Saint-Sorlin, a leading writer hostile to Port Royal. In the first (December 1665) Nicole ventures the generalization that "a novelist and a dramatic poet is a public poisoner, not of the bodies but of the souls of the faithful..." Though Racine had no need to take this attack as directed against himself, the malicious anonymous reply (*Lettre à l'Auteur des Hérésies imaginaires et des Deux Visionnaires*, 1666), which he subsequently avowed, could indeed be explained by the hypersensitiveness of a young poet rushing almost quixotically into the lists. But the evidence also suggests another motive: readiness to curry favour with the public enemies of Port Royal at a time when Port Royal was under attack. According to his son, Louis, Racine refrained, on Boileau's advice, from publishing further venomous contributions to a controversy which continued well into 1667. He probably knew, from a letter to Vitart from Lancelot (May 18), how critical the latter was of "faults of judgment" in the works he had published. He knew that his only self-defense in terms of his humanistic education was to reply in kind; and when, having in the course of the next ten years produced his seven masterpieces from *Andromaque* to *Phèdre*, he comes again, in his preface to the latter play (1677), publicly to address the former teachers whom he had so cruelly attacked, it is with the plea that he has shown in *Phèdre* that tragedy can still be, as it had been with the Ancients, a school of virtue.

Andromaque was presented before the king and queen in the queen's apartments on Nov. 17, 1667. The title role was played by Thérèse Du Parc, who had been the most beautiful actress of Molière's troupe and whom Racine seems to have enticed to join the *Comédiens du Roy* at Easter 1667. She continued to interpret his leading roles until her death in 1668. Opinion viewed them as lovers, and the evidence that he was present at her death and was deeply shaken by it, seems conclusive. That she was poisoned is less sure, and it is still less sure that they were secretly married (these assertions were made by the famous poisoner, "La Voisin," at her trial in 1679; see POISONS, AFFAIR OF THE); but there is evidence that they had a daughter who died at about the age of eight.

In *Andromaque*, developing a theme indicated in Virgil, drawing upon plays of Euripides and Seneca, and influenced also by Corneille's *Pertharite* (1652), Racine presents Oreste in love with Hermione, Hermione with Pyrrhus, and Pyrrhus with Andromaque, his captive, Hector's widow. Pyrrhus threatens that if she persists in refusing him he will hand over her son, Astyanax, to Oreste, who in the name of the Greeks has come to demand his surrender. Andromaque, torn between fidelity to her dead hero and the wish to save her child, finally accepts Pyrrhus' offer, secretly resolving to kill herself at the altar once the marriage vows have been exchanged. Hermione, driven by jealous rage, sends Oreste to kill the faithless Pyrrhus as proof of his own (Oreste's) love for her. The reluctant deed done, she turns on him, disclaims responsibility, and rushes out to slay herself on the dead body of Pyrrhus, while Oreste becomes a prey to the Furies. In this play Racine presents the passion of love carrying all before it and destroying its victims. To the ability already revealed in *La Thébaine* to contrive a strong plot and to give powerful expression to the passions, and to the verbal facility shown in *Alexandre*, Racine here adds an ability to interpret and express the deepest feelings of the heart. His *Andromaque*, in her fervent and single-minded devotion to the dead Hector, is as moving as his fierce Hermione, whose successive pleas and reproaches to Pyrrhus (Act IV) and denunciation of Oreste (Act V) are among

the great things in dramatic literature. The play enjoyed a success comparable to that of Corneille's *Le Cid* 30 years before.

Racine's next play was a three-act verse comedy, *Les Plaideurs*, given in the latter part of 1668 and published in December. He first planned to write for the Italian actors (who shared the stage of the Palais-Royal with Molière's company) a skit in the manner of Aristophanes' *Wasps*. When the famous Scaramouche (Tiberio Fiorelli) left Paris, he adapted his scheme to the French stage. He claimed that the idea came to him from an obscure lawsuit concerning a benefice in which he was involved. Aristophanes' attack on the Dicasts inspired him to give expression to his own irritation at the pedantries of the law. But his Dandin—corresponding to the Greek Philocleon and also owing something to Rabelais—stands in his own right as one of the permanent comic types of French comedy: the judge so intent on judging that he gets up in the middle of the night to judge and has to be kept in his home by his son and the porter. The final scene in which he presides at the trial of the dog which has run off with a capon is the *reductio ad absurdum* of Dandin's profession. Among the characters Racine introduced into this Aristophanic situation are the comtesse de Pimbesche, the incorrigible *plaideuse* (litigant); the incorrigible *plaideur*, Chicanneau, with whom she vies; and the young couple who, duping their elders, bring this brilliant trifle to a conventionally happy conclusion. In this, his only comedy, Racine showed a wide variety of comic gifts and adapted the Alexandrine to comic uses in masterly fashion. The king's enjoyment of the play turned opinion in its favour; and it has held the boards of the Comédie Française ever since.

Racine had already challenged Corneille with *Alexandre*, only to be reprimanded by Saint-Évremond (*q.v.*) for lack of a sense of history. In returning to tragedy with *Britannicus* (performed Dec. 13, 1669; published January 1670), he meets Corneille more directly and advisedly on the consecrated ground of Roman history. Taking his subject from Tacitus, he gives a masterly picture of the imperial despotism at the moment in history when Nero cunningly and ruthlessly frees himself from the tutelage of his dominating mother, the dowager empress Agrippina, by contriving the death by poisoning of his rival Britannicus. His tragedy, Racine explains, is at once the fall of Britannicus and the disgrace of Agrippina; and he intensifies the conflict by making Nero and Britannicus rivals for a Junie whose innocence shares no trait with her supposed Roman prototypes. While Nero is only shown as the "monstre naissant," Narcisse is presented as the wholly evil counselor of his imperial master. Burrhus represents the stoic virtues in a setting in which they fail to restrain the violence of Nero, even if they give it momentary pause. With its careful study of the imperial despotism and its verse of bronze—nowhere more impressive than in the great speech in which Agrippina momentarily resumes her authority over her son—*Britannicus* has for long been recognized as "la pièce des connaisseurs" (Voltaire). If *Andromaque* presented in all their terrible beauty the passions of tragic love, *Britannicus*, while giving these full poignancy, presents a study of evil in a setting close enough to the realities of the French court to make eloquent sense.

Though the play did not enjoy the success of *Andromaque*, it has gradually imposed itself as Racine's great Roman tragedy. Racine again treated a Roman subject with *Bérénice* (Hôtel de Bourgogne, Nov. 21, 1670), though the theme is a very different one—a poignant parting of lovers: Titus, though he loves, and is loved by, the Palestinian Queen Berenice, sends her away when he becomes emperor. Racine refers to Suetonius as the source of this, the simplest of his tragedies. Racine's intermediary between the new emperor and Berenice, Antiochus, king of Commagene, has himself long cherished an unanswered passion for the queen. With these three characters, supported by their confidants, Racine builds up a tragic tension—each character in turn threatening suicide if the other makes away with him or herself—finally resolved by Berenice herself in a speech of renunciation which is one of the most moving and beautiful things in all tragedy. A story neither disproved nor finally confirmed was put about by Boileau in his latter years, that Henrietta of England (Henriette d'Angleterre), duchesse d'Orléans, invited Racine to treat this

subject, no doubt because of the parallels with the relationship of Louis XIV and several great ladies, particularly Henrietta herself and Marie Mancini, Mazarin's niece. Evidence does not bear out Fontenelle's addition—that Henrietta invited Corneille as well as Racine (each without the other's knowledge), to treat the same theme; but it seems likely that Corneille's *Tite et Bérénice*, *comédie héroïque*, performed by Molière's troupe on Nov. 28, 1670, was composed with knowledge of Racine's text and in rivalry with it.

With *Bajazet*, performed early in January 1672, Racine broke new ground with a subject drawn from recent Ottoman history. The young prince, Bajazet, and the innocent Atalide, a young Ottoman princess, are presented as the victims of the jealousy of the ferocious sultana, Roxane, and of the intrigues and ambitions of Acomat, the grand vizier. In contrast with those of *Bérénice*, all three characters of *Bajazet* suffer violent death. Roxane's violent and purely possessive love is depicted with the overtones of Oriental passion; and the despotism of the seraglio, with its mutes, its slaves, its stranglings, is powerfully suggested; but the idiom and vocabulary of the classical Alexandrine remain the same. Distance in time, which made heroes drawn from antiquity acceptable, is here replaced by distance in space. The tragedy was played in costumes and décor "à la turque."

With *Mithridate* (January 1673), Racine again openly vies with Corneille in presenting a subject of epic dimensions; the resistance to Rome and the heroic death of one of Rome's greatest opponents, Mithradates VI. Mithradates, emerging powerfully from utter defeat, plans to lead his resurgent forces across more than half the known world to strike at the heart of the oppressive republic. Racine presents this Oriental despot as the rival with his sons for the Greek princess Monime, the noblest and the most touching of his creations. In his old man's jealousy Mithradates resorts to ruthless trickery and reveals all the symptoms of a man carried away by passion. After fighting the Romans to the last, he turns his sword upon himself, and, knowing that he is dying, gives Monime to Xipharès, the son who had remained true and withstood the Romans—the only example in Racine of a hero rising above himself in the Cornelian manner, even if only *in extremis*. It is not surprising that this was the one of Racine's tragedies which Louis XIV most admired.

Racine had been elected to the Académie Française on Dec. 5, 1672, and his reception by it on Jan. 12, 1673, at the time of the triumph of *Mithridate*, marks the height of his fortunes as a successful dramatic poet enjoying royal favour. In October 1674 he was awarded a lucrative sinecure as "trésorier de France," an office which conferred nobility.

He seems at about this time to have resumed intensive study of the Greek tragic poets, especially Sophocles. *Mithridate*, in several of its moments and in the touching and serene figure of Monime, provides evidence of this. For his next subjects, Iphigenia and Phaedra, though not without debts to contemporary or earlier French dramatists, he went back to Euripides.

His *Iphigénie en Aulide* was acted on Aug. 18, 1674, in the park of Versailles. As is known from a surviving prose fragment, Racine was first attracted by the theme of *Iphigeneia in Tauris* but abandoned it for a free adaptation of the other Euripidean tragedy of *Iphigeneia in Aulis*, in which Agamemnon is presented as conniving, against his own fatherly affections, in the sacrifice of his daughter, so that Calchas' prophecy may be fulfilled and the ships sail for Troy. Racine presents with power and poignancy the conflict which first opposes Agamemnon and Clytemnestra; Achilles appears in character fierce, relentless, ready to oppose his Agamemnon in arms; while Iphigénie is touchingly depicted as the affectionate daughter. But Racine avoids either shocking his audience or provoking their incredulity by introducing another "Iphigénie," Ériphile, an unsuccessful rival for Achilles' affections. Her jealousy, envy, and violence make us accept the application to herself of the words of the oracle and her self-immolation as a sacrificial victim.

Iphigénie was another triumph for Racine. He had now to contend, however, not only with the aging followers of Corneille, but with several younger rival dramatists and the spreading cult of

opera. This transpires from the polemical part of his preface to the published play. While all his prefaces are, indeed, in part polemical, the earlier ones—particularly those of *Britannicus* and *Bérénice*—had already shown his positive concern with tragic doctrine. And now his ideas found a champion in Boileau's *L'Art poétique* (1674). Boileau had become a treasured literary counselor; and there is evidence that Racine when composing his next play also submitted it to the other leading critics of the day: the *pères* Rapin and Bouhours.

This play, at first entitled *Phèdre et Hippolyte*, and acted on Jan. 1, 1677, goes back to the Hippolytus of Euripides, but also draws substantially upon Seneca's play on the same subject and has smaller debts to modern dramatists—two of whom, Gilbert and Bidar, had, unlike Euripides and Seneca, made their Hippolytus susceptible to love. Racine presents Phèdre (Phaedra) as dying of a hidden passion for her stepson, which she confesses to her nurse Oenone. Following the report of the death of her husband Thésée (Theseus), she finally declares her love to the horrified Hippolyte. When news comes that Thésée is not dead and is returning, Phèdre acquiesces in Oenone's calumny of Hippolyte; and Thésée, in his fury, calls upon Neptune to avenge him. Phèdre is about to exculpate Hippolyte when she learns that he has defended himself by confessing his love for Aricie, a daughter of a hostile race. Thésée has refused credence; but Phèdre knows in her heart that Hippolyte's avowal must be true and gives herself up to jealousy and despair: hell gapes and she has a vision of her father Minos sitting in judgment in the Underworld. Hope has been raised that Hippolyte and Aricie may escape the wrath that threatens them but Hippolyte has been dragged to his death by his own chariot horses startled by a monster sent from the sea in response to Thésée's prayer. Phèdre, who has taken poison, confesses her guilt and dies on the stage; and Thésée proclaims his adoption of Aricie. Though characters and plot are carefully balanced, Phèdre holds the attention and stirs the emotions from the outset. She is, as much as Hermione or Roxane, a prey to overwhelming passion; but is at the same time pitiless in her self-condemnation, and sublimely alive to the better course which she cannot follow. Racine has succeeded in engaging us in her fate despite her guilt and in stirring all our pity as well as our fear. Phèdre comes to us, like Oedipus or Lear, a sacrificial victim representing the human condition in all its awareness and helplessness.

Racine's "Retraite."—Though Racine's genius surpassed itself in *Phèdre*, the play encountered opposition. The duchesse de Bouillon's faction had engaged a young dramatist, Nicolas Pradon, to treat the same subject in a play, *Phèdre et Hippolyte*, produced two days later than Racine's at the Théâtre Guénégaud. Boileau stood by his friend, and, in his seventh verse epistle, lauded the qualities he had displayed as a tragic poet and stressed the astringent value of hostile criticism. But the violent conflict and threats only served to bring out Racine's dependence as a tragic poet upon the vicissitudes of theatrical life. After the death of La Du Parc, his name had been linked with that of a second, even more noted, actress, "La Champmeslé," who had joined the Hôtel de Bourgogne in the spring of 1670 and had thereafter created Racine's leading female roles. Racine tutored her in her parts, which she is reported to have spoken and played divinely. Plausible gossip makes her share her favours between a more than complacent husband, Racine, and a variety of other lovers, several of them noblemen of high rank.

There is no evidence that Racine's debt to La Champmeslé was greater or less in *Phèdre* than in his other plays since *Bérénice*; but the preface which accompanied the play when it was published on March 15, 1677, strikes a new note. In no work of his, he declares, has virtue been given more emphasis than in this. The slightest faults are punished and vice is painted in all its horror. Such had been the aim of the first tragic poets; and Racine concludes his preface with the gesture of conciliation to Port Royal mentioned above.

Though the nomination of Boileau and Racine as historians of the great reign, which they owed to Mme de Montespan, was not known until autumn 1677, it seems likely that it was provisionally decided early in the year, and the acceptance of such duties in-

volved Racine's abandonment of direct connection with the theatre. His carefully prepared marriage with Catherine de Romanet, a good *partie* of a family of La Ferté-Milon, took place on June 1, 1677. She had never read any of his plays and, to the end of her life, "did not know what verse was." His life was thereafter divided between his duties at court and his Paris home, where between 1678 and 1692 he became the father of two sons and five daughters. The youngest, Louis Racine (1692-1763), was the author of two didactic poems notable for their clarity and Jansenist piety: *La Grâce* (1720) and *La Religion* (1742). The latter, a verse apologia based on Pascal's *Pensées*, was particularly successful, being classed by La Harpe with Pope's *Essay on Man*. He also wrote *Mémoires sur la Vie de Jean Racine* (1747; prefacing an edition of his father's works), containing valuable information, as well as much hearsay, mainly derived from Boileau. They must be read with caution because of his wish to whitewash his father. His *Remarques* (1752) on his father's tragedies paid attention to their classical sources.

Much discussion has taken place regarding Jean Racine's so-called *retraite* which (as Mme de la Fayette wrote in her *Mémoires*) withdrew the "best poet of his age from his poetry, in which he was inimitable, to make of him . . . a very imitable historian." His duties involved following the king in his campaigns. He was also required, as member of the Académie des Inscriptions, to choose the themes and Latin legends for the "Histoire métallique," a commemoration in medals of the great reign. He was nearly involved in composing with Boileau—at Mme de Montespan's behest—a libretto for an opera on the fall of Phaëton; and he wrote words for an *Idylle sur la Paix*, set to music by Lully and performed on July 16, 1685, before the king at Sceaux.

He returned unexpectedly to dramatic poetry, if not to the stage, with *Esther* and *Athalie*—both based on biblical material and written at the request of the king's new consort, Mme de Maintenon, for performance by pupils of the school she had founded for daughters of the poorer nobility at Saint-Cyr; and he took the opportunity to reintroduce the chorus into tragedy. *Esther*, produced at Saint-Cyr in January and February 1689, presents in three acts the story of the Jewish wife of the Persian King Ahasuerus, who, exhorted by her uncle Mardochée (Mordecai), a powerful prophet-figure, succeeds in confounding in the royal presence the wicked Haman who has sought to have her people massacred. Her triumph is celebrated by rapturous chants of thanksgiving sung by the chorus of Israelite maidens.

Racine's dramatic ambitions were rekindled by the triumph of this pious play at a court where religious devotion had become fashionable, and the outcome was *Athalie*. It presents an earlier biblical story: the restoration of Joash to the throne of David and the destruction of Athaliah, the impious daughter of Jezebel. Racine's *Athalie*—in whom some of the traits of Agrippina and Phèdre, with echoes of the Clytemnestra of Sophocles' *Electra*, come together with great effect—is a figure so arresting that she gave her name to a play which should properly have been entitled "Joas Reconnu et mis sur le trône" (Racine's preface). God's instrument in the restoration of Joas is the high priest Joad (Jehoida), perhaps the most powerful of all Racine's creations. Though responses to this great play have varied somewhat as political or religious sympathies dictated, Racine succeeded in building up a poignant interest in the fate of the young king and in his relationship with his foster-parents—the high priest and his wife, Josabeth, who, in a situation fraught with political and transcendental tensions, movingly and beautifully embodies maternal solicitude. At the very centre of this play, the setting of which is the Temple of Jerusalem, he puts into the mouth of his fighting high priest a prophecy of the birth of the Messiah, thus emphasizing the religious character of a work which has been felt to be closer in spirit than any other of modern times to ancient tragedy despite its Judæo-Christian inspiration.

Owing to clerical intervention *Athalie*, unlike *Esther*, was performed without *décor* or costumes, before a limited audience in a classroom of Saint-Cyr in January 1691; and though it received a more spectacular performance at court, it was never, during Racine's lifetime, represented as he had intended. The lyrical

beauty of the choruses, based upon the Psalms and passages from the Prophets, and the spectacular conclusion, made such a realization the more difficult.

His last poetical works, the four *Cantiques spirituels*, also based on biblical texts, were set to music (three by Jean-Baptiste Moreau, composer of the music of *Esther* and *Athalie*; one by Michel de Lalande) and performed in the royal presence (1694).

The history of the reign upon which he and Boileau were engaged was destroyed in a fire which burned down the house of his friend Valincour, who succeeded him as academician and historiographer; but his work as historian is shown in the incomplete and very different *Abrégé de l'Histoire de Port Royal* (published 1767), a secretly and objectively composed apologia of an institution the interests of which he used his good offices at court to defend in his latter years. He had received further advancement when he became *gentilhomme ordinaire* (December 1690), and early in 1696 he was nominated one of the 50 *conseillers secrétaires du Roi*. He was in frequent touch with the king and was called upon to read to him in periods of illness and sleeplessness. The charge of Jansenism seems to have underlain an eclipse of royal favour in 1698. His biographers agree as to the genuine humility with which he faced this and the illness of his last two years. He died in Paris on April 21, 1699. In his will he asked to be buried at Port Royal des Champs. When Port Royal was destroyed by royal decree (1710), his remains were taken to Paris and reinterred at Saint-Étienne du Mont.

Character, Reputation, and Poetic Genius.—All the evidence points to Racine's paramount desire to succeed at all costs as a tragic poet in an age when patronage was all-important. An exact contemporary of Louis XIV, and gifted with all the social graces, he chose, when private problems and professional rivalry counseled abstention, to consolidate his position at court and to renounce the tragic theatre, of which he had become the acknowledged master.

Already recognized as a classic in his own age, Racine came in the 18th century to replace Corneille as the leading representative of French tragedy. Voltaire, who claimed to be his successor, acknowledged his supremacy. But for Schlegel, and still more for Stendhal, he primarily represented the *ancien régime* and its religious, political, social, and literary conventions, to which he had given perfect expression. No major dramatist has indeed since then sought to revive the French classical convention. But, despite the Romantic explosion, and the wide variety of works seen in Paris, French and foreign, past and present, it is Racine's tragedies from *Andromaque* onward, and the four most notable of Corneille, which still constitute the core of the tragic repertory of the Comédie Française, a company which can claim to be the direct inheritors of the tradition of the *Comédiens du Roy* who first acted Racine's masterpieces under his direction.

Racine entered the lists at a time when Corneille had written his masterpieces, and had, in his *Discours* on dramatic art (1660) and his *Examens* (which he attached to each of his dramas written up to that time), reconsidered his own practice in the light of an ideal of regularity which found its strictest expression in the abbé d'Aubignac's *La Pratique du Théâtre* (1657), with its rigorous formulation of the three unities of space, time, and action. Gradually refining upon the accepted pattern in the light of his own experience of the theatre, his knowledge of ancient poetry and theory, and his growing responsiveness to human passions and situations, and gradually reducing to a minimum the contemporary "precious" elements of social convention, Racine produced a series of tragedies unique for their range, power, concentration, expressiveness, and strictness of form—and for a felicity of style on occasion so exquisite as to have become associated in our time with a conception of "pure poetry" quite dissociated from the dramatic and tragic purposes its author intended. It is as a great tragic poet that he claims to be judged—and as one whose high dramatic qualities are inseparable from the language in which they find unique expression.

BIBLIOGRAPHY.—*Editions, etc.*: The first collected edition of Racine's works appeared in 1675-76, and the last revised by him in 1697. A new collected, annotated edition was published by his son Louis in 1747.

The first complete critical edition (with critical life, and L. Racine's *Mémoires*) was that by P. Mesnard in *Collection des Grands Écrivains de la France*, 8 vol., with supplements (1865-70; 2nd ed., 1885-88). A new critical edition of the *Oeuvres complètes* (also with the *Mémoires*) by R. Picard appeared in the *Pleiade* series, 2 vol. (1950-52); Picard also published *Corpus Racinianum*, a collection of contemporary documents concerning Racine (1956; *Supplément*, 1961). Both the Mesnard and Picard editions contain the posthumous writings, correspondence, and notes on Homer, the Greek tragic poets, and other, mainly ancient, writers. Useful collected editions of the plays include those by A. Debidour (1948) and P. Mélése, 5 vol. (1951). Notable editions of separate plays are *Bérénice* by W. S. Maguiness (1929); *Bajazet* by C. M. Girdlestone (1955); *Mithridate* by G. Rudler (1943); and *Phèdre* by R. C. Knight (1943). See also the *Mise en Scène* with text of *Phèdre*, by J.-L. Barrault (1946).

Williams, *Racine depuis 1885: bibliographie raisonnée* (1940); Frantz Calot, *Les Portraits de Racine* (1941); *Cahiers raciniens*, ed. by L. Vaunois, Société racinienne (1958-); *Jeunesse de Racine* (1958-), and *Actes du 1^{er} Congrès international racinien* (1962), both ed. by J. Dubu.

Translations: Despite the impossibility of doing justice to Racine in translation there are acceptable modern blank verse versions by R. Henderson and P. Landrin (1931, new ed. 1959; *Andromache, Britannicus, Phaedra, Athaliah*); by Kenneth Muir (1960; as above, with *Berenice*); and by J. Cairncross (1964; *Iphigenia, Phaedra, and Athaliah*). The most successful modern rhymed versions, in heroic verse, are Harold Bowen's *Britannicus* (1948), and Robert Lowell's *Phaedra* (1963). (W. McC. S.)

RACINE, a city of southeastern Wisconsin, U.S., situated on Lake Michigan at the mouth of the Root River, 25 mi. (40 km.) S of Milwaukee and 65 mi. (105 km.) N of Chicago. It was founded in 1834 by a lake captain, Gilbert Knapp, and quickly obtained settlers in the first important American population movement into southeastern Wisconsin in the late 1830s. At first it was called Port Gilbert after its founder but in 1837 it adopted the French name of the river on which it stands and in 1848 it was incorporated as a city. Pop. (1960) city 89,144, of which about 10% was foreign-born white (mainly from Denmark, Germany, Czechoslovakia, Italy, Russia, Poland, and Lithuania). The standard metropolitan statistical area (Racine County) had a population of 141,781. (For comparative population figures see table in WISCONSIN: *Population*.) Industry began to develop shortly before the American Civil War and Racine became an important centre for farm machinery at an early date. Its industrial development received a considerable impetus from World War II and was exceedingly diversified. Among its more important industrial products are tractors and farm machinery, automobile accessories, power tools, iron and steel castings, electrical products, floor wax, malted milk, leather goods, and furniture. The city is served by the Racine extension division of the University of Wisconsin, which provides two years of accredited college work. Racine possesses an extensive park system including recreational areas and Zoo Park.

(RE. H.)

RACKETS (RACQUETS) and SQUASH RACKETS are games played in an enclosed court with a ball and a racket. Rackets, the older game, is played in a large court with a hard ball and squash rackets in a smaller court with a soft ball.

Introduction.—Attempts have been made to trace rackets, like tennis, to an ancient origin; but the game as now known can hardly be said to have existed before the 19th century. In England, the first school that took to rackets was Harrow in the 1820s. In the middle of the 19th century the game achieved standing in England, but by the 1930s the expense involved reduced the amount of play outside British public schools, and many courts were converted into squash courts. As rackets declined, squash rackets, much cheaper to play, caught on. Curiously, squash started at Harrow some years later as a soft-ball game of rackets. It was not until after World War I that squash achieved popularity beyond the public schools and country houses and came to be recognized as an excellent game (because of the maximum exercise it afforded in the minimum time) to help maintain physical fitness.

Rackets was first played on the North American continent in Canada, being well established in the second quarter of the 19th century. The known first court was built in Montreal in 1836. The first definitely recorded court in the United States was built in New York in 1850. The game was played in a few clubs in a half-dozen cities and the Racquet and Tennis Club of New York was the game's stronghold. But here again the number of courts and players dwindled because of the expense and because of the popularity of squash.

RACKETS

In rackets the racket, for which no specific dimensions are laid down, is about 2½ ft. (about 76 cm.) long and the head, strung with catgut, 7 or 8 in. (about 178-203 cm.) in diameter. Made of ash, its average weight is about 9 oz. (about 255 g.). The ball, which has a renewable covering of adhesive tape, is 1 in. (2.54 cm.) in diameter and weighs 1 oz. (28.35 g.).

The Court.—Most courts are about 60 ft. (18 m.) long by 30 ft. (9 m.) wide and accommodate both the single and double, or four-handed game. Courts have four walls. The roof, where skylights or other lighting is placed, is out-of-bounds for play; in India courts were left unroofed. The cement floor and walls must be perfectly smooth and very hard since the faster the ball travels the better the game. Front and side walls are about 30 ft. (9 m.) high, the back wall being about half that height with a spectators' gallery (containing the marker's box) above it. The court is entered by a door in the centre of and flush with the back wall. On the front wall is fixed a wooden board, the upper edge of which, 27 in. (.68 m.) from the floor, constitutes the play line; 9 ft. 7½ in. (2.93 m.) from the floor a second line called the cut line or service line is marked. On the floor, 35 ft. 10 in. (10.92 m.) from the front wall and parallel to it the short line runs from wall to wall. From the centre of the short line to the centre of the back wall, the fault line divides the space between the back wall and the short line. These latter rectangles are the service courts. Against the side walls and separated from the service courts by the short line are the service boxes.

The Game.—Rackets is played by two persons (singles) or four persons playing two against two (doubles). The object of the players is to return the ball either before it reaches the ground or on its first bound so that it strikes the front wall above the play line (or service line in the case of a serve) and returns into the court, and to continue to do so alternately (either player of each in doubles) until one player fails to make a valid return and loses the stroke. The ball must not go out of court (into the gallery or roof of the court) or touch the players' clothing or person. Hard, low hitting close along the side wall is the essence of the game, with cutting, volleying, half-volleying, drop shots, and angled shots also in the repertory. In the four-handed game one of each set of partners takes the right-hand side of the court and his partner the left. The game consists of 15 points called aces. Aces can be scored only by the hand-in (the player, or side, having the service) and the hand-out (receiving service) must therefore win

a stroke or strokes to obtain service before he or they can score an ace. In doubles each of the partners serves in turn; both must therefore be ousted before handout obtains the service; except that in the first hand of each game only one partner has service.

The server, with at least one foot inside the service box, serves the ball as in tennis, but directly to the front wall above the service line so that it rebounds and hits the floor within the service court on the opposite side, permissibly striking the side wall, back wall, or both before or after touching the floor. The serve is a fault if the ball (1) strikes the front wall below the service line; (2) touches the floor on the first bounce in front of the short line; or (3) touches the floor, on its first bounce, in the wrong court. If the hand-out player chooses to take a faulty first serve, play proceeds as if the serve had been good; otherwise the server must serve again; if he serves a second fault he loses his hand or innings and his partner or opponent, as the case may be, takes his place. In the United States and Canada only one serve is permitted. A serve that makes the ball strike the board, or the floor before reaching the front wall, or that sends it out of court, counts the same as two consecutive faults: it costs the server his innings.

Skill in service is most important. A combination of cut (making the ball spin so that it rebounds at varying angles) and pace can make the service very difficult to return, and service aces are more frequent in rackets than in squash rackets. Rackets courts vary in pace, and this too influences service.

The server may begin in either of the service boxes and proceeds alternately from one to the other until put out. The other side may then also begin in either box. In doubles the serve is taken alternately by the two hand-out players who permanently occupy the right- and left-hand courts, being allowed to change the order in which they receive the service at the end of any game or rubber.

If hand-out succeeds in returning the serve, the rally proceeds. If hand-out fails in the rally (or in receiving service), hand-in scores an ace and the side that first scores 15 aces wins the game. When, however, the score reaches 13-all, hand-out may, before the next serve is delivered, declare that he elects to set the game either to 5 or 3, making the game 18 or 16 points, whichever he prefers; and similarly when the score stands at 14-all, hand-out may set the game to 3 (game 17).

It is the player's first duty to give the opponent full room for his stroke, but it is not always easy and sometimes, especially in doubles, absolutely impossible not to obstruct him. The rules, therefore, carefully provide for "lets." When in matches a let is claimed by any one of the players and allowed by the referee, the service or rally counts for nothing and the server serves again from the same service box. The server in possession at the end of a game continues to serve in the new game, subject as before to the rule limiting the first innings of a doubles game to a single hand.

The usual number of games in matches is five for singles and seven for doubles. In matches where there is a referee, there is an appeal to him from the marker's decision but no appeal is allowed if a foot fault is called.

SQUASH RACKETS

Squash rackets, often called squash, is played on exactly the same principle as rackets, by two players only. The rules are in most particulars similar, but the scoring is different. In England, hand-in only can win an ace. A game consists of 9 points; if, however, the score becomes 8-all, hand-out has the option of a set to two—making the game 10 points. In the United States a game consists of 15 points, and an ace is scored for each rally irrespective of which player is serving; at 13-all, hand-out may set to 5 points (game 18), to 3 points (game 16), or no set (game 15).

Doubles games are also played in the U.S. and Canada. In both countries a rubber consists of the best three out of five games. The squash racket is similar to that used in the game of rackets, but the handle is shorter, and the U.S. racket is heavier than the British. The ball is of rubber or rubber and butyl com-

position. The ball used in the U.S. is larger than that in England.

The Court.—The standard British court has four walls, which are of wood or composition, and can either be covered or uncovered. The dimensions and markings of the British court are shown in the accompanying diagram. The board, or telltale, is a strip of sheet metal or other resonant material that produces a clearly different sound when the part of the front wall "in play" or "out-of-play" is hit. The standard U.S. court is considerably narrower than the English, being 32 ft. by 18 ft. 6 in. (5.64 m.). The playing area of the front wall is 16 ft. (4.9 m.) high and the side walls are 16 ft. (4.9 m.), extending back 22 ft. (6.7 m.), from which point they may be 12 ft. (3.7 m.) high. The playing area

DIMENSIONS AND MARKINGS OF A BRITISH INDOOR SQUASH RACKETS COURT

of the back wall is 6 ft. 6 in. (2 m.) high. The top of the play line and top edge of the telltale is 17 in. (43 cm.) and of the service line 6 ft. 6 in. (2 m.) from the floor. The short line, or service court line, is 10 ft. (3 m.) from the back wall, and the service boxes are in the shape of a quarter circle, of 4 ft. 6 in. (1.4 m.) radius, from the intersection of the short line and the side wall on each side. Doubles courts are 45 ft. (13.7 m.) by 25 ft. (7.6 m.); front walls are 20 ft. (6.1 m.) high; side walls 20 ft. for 31 ft. (9.4 m.) and 15 ft. (4.6 m.); back walls 7 ft. (2.1 m.); and service lines 8 ft. 2 in. (2.5 m.); and service court lines are 15 ft. (4.6 m.) from the back walls.

Competitions.—*Great Britain.*—Open competition in squash rackets started after World War I, the Amateur Championship (1922), the Professional Championship of the British Isles (1920), and the Open Championship of the British Isles (1930) being the most important. Players from South Africa, Egypt, Australia, and Pakistan have generally dominated championship play.

During November–April many tournaments take place, including county and intercounty championships, and the Bath Club Cup and the Cumberland Cup in the London area. International matches are played between the countries of the British Isles, and between Great Britain, Australia, and South Africa.

The British Women's Championship, held in London, attracts a large entry and since 1962 has been won by Australian players. There are tournaments held for juniors culminating every April in the Drysdale Cup, the unofficial junior championship, whose entry includes players from India, Denmark, and the Netherlands.

United States.—The first courts constructed in the United States, as far as is known, were at St. Paul's School in Concord, N.H., in the early 1880s. The development of the game was more rapid in the United States than in England, and it achieved great popularity in the late 1920s and 1930s. Many courts were built in the large cities, particularly in New York, Boston, and Phila-

delphia. The game is also played in Canada. British teams visited America after 1924, and U.S. teams also toured in England, but competition between the two countries is hampered by the considerable differences in the ball, the court, and the methods of scoring which exist between the games.

Collegiate, amateur, and women's competitions are prominent in the U.S. In 1933 a biennial international team match for the Wolfe-Noel Cup was started between British and U.S. women.

Other Countries.—Since World War II the game has made tremendous strides in several countries, particularly in Australia, where in Sydney alone there were more than 400 courts. In South Africa the game is also growing. In the 1960s clubs and national associations in 35 different countries of the world were affiliated to the Squash Rackets Association.

In Europe the game is not played as much as it is elsewhere, but national championships are held in Belgium, Denmark, Greece, the Netherlands, and Sweden. In 1966 an International Squash Federation was formed by Great Britain, Australia, India, New Zealand, Pakistan, South Africa, and the U.A.R. to promote the game and to coordinate tour and team championships between the nations.

Squash Tennis.—Another game of squash, known as squash fennis, is played in the United States. It had a bigger following than squash rackets until the rise in popularity of the latter game in the late 1920s, after which, since squash tennis is not played at the colleges, the number of players dwindled. By the 1960s it was largely extinct, being kept alive by only a comparative handful of players at a few university clubs in New York City.

Squash tennis is played in the same court as is squash rackets, a combination court for the two games having been adopted in the 1930s; there are minor differences, including service-line markings. In squash tennis a modified lawn tennis racket is used and the ball is inflated, traveling with great speed around the walls, at times rebounding from the front wall to the rear wall and even to the front wall again.

RADAR is an electronic device which provides man with the ability to detect and locate objects of a certain sort at distances and under conditions of lighting or obscuration which would render the unaided eye quite useless. Further, radar affords a means for extremely precise measurement of the range, or distance, to each of the objects it detects and locates—or “sees.” It can also measure the speed of such an object toward or away from the observing station in a simple and natural way.

Radar is superior to the eye because it can “see” regardless of visibility conditions and because it affords an easy and accurate means for measuring target range and its rate of change. Largely because of the lack of detail in radar vision, the class of objects usefully seen by radar is smaller than the class distinguishable by the eye. Radar deals best with isolated targets in a relatively featureless background: aircraft in flight, ships on the open sea, islands and coast lines, and the like.

This article is divided as follows:

I. INTRODUCTION

How Radar Works.—Radar is an acronym derived from the initial letters of the phrase “radio detecting and ranging.” Radio waves sent out from the powerful radar transmitter are reflected by objects within range of the set. A tiny fraction of the outgoing energy returns as an echo to the radar receiver, which is usually located at the same place as the transmitter. The properties of the received echo are used to form a picture or to determine certain properties of the object which caused the echo. As we shall see later on, there are several different forms of radar systems, making use of different properties of the received echo and involving different sorts of radio transmissions from the radar transmitter. The form employed in the majority of the sets is pulse radar. When the word “radar” is used without qualification in this article, pulse radar will be meant.

Pulse radar is so called because the transmitter is keyed to send out short, very intense bursts or pulses of energy with a relatively long interval between pulses. The receiver receives echoes from the nearest objects soon after the transmission of the pulse, from objects at intermediate range later on and from the most distant objects near the end of the interpulse interval. When sufficient time has elapsed to permit the reception of echoes from the most distant objects of interest, the transmitter sends another short pulse, and the cycle repeats.

The delay between the transmission of the pulse and the reception of the echo is due to the fact that the radio waves used travel with the great but finite speed of light. In the units convenient in radar, the speed of light (about 186,000 miles per second) is 328 yd.¹ per millionth of a second, or microsecond. Since the radio energy from the radar transmitter must travel the distance from the radar to the target twice, once out and once back as an echo, each microsecond of delay between the transmission of a pulse and the reception of an echo corresponds to 164 yd. of range between radar set and target. If the delay corresponding to target range R is called T_R , it will be given by

$$T_R = \frac{2R}{c} \quad (1)$$

where c is the velocity of light.

This is the clue to the accuracy with which range can be measured by radar. Range measurement is reduced to the measurement of time, which can be performed more accurately than the measurement of any other basic quantity of physics. Very short intervals must be timed to get absolute precision in range, of course; if an error in range of only five yards can be tolerated, time intervals must be measured with an accuracy of one-thirtieth of a microsecond. Electronic timing and display techniques developed during World War II enabled such measurements to be made with great ease and convenience.

In 1945, for example, a serious map error was discovered by the use of bombing radar. This equipment enabled a bombing plane to find its position accurately by measuring the ranges to two fixed ground stations at which radar beacons (see below) were located. One beacon station was on the island of Corsica. A miss of about 1,000 yd., nearly 50 times the error expected, was scored on the first bombing mission carried out in Italy with this system. After an investigation of all possible sources of error, it was suggested that the reputed position of Corsica might be wrong. A correction of about 1,000 yd. in the position of the island was used on the next bombing run. The results, and those of later missions that used the corrected position of the island,

¹This is about 1,000 ft. (984) in one microsecond.

FIG. 1.—ELEMENTS OF A CATHODE-RAY TUBE

were indistinguishable from those of optical bombing.

A cathode-ray tube (CRT) is almost always used for the display of radar signals. This device, shown schematically in fig. 1, has an "electron gun" at the base of its glass envelope, deflection plates or coils in the neck of the tube and a luminescent screen on the inside of the large, nearly flat face of the tube. The electron gun produces a narrow, accurately focused beam of electrons which is aimed toward the centre of the screen. This pencil of electrons can be deflected in its flight from gun to screen either by electric fields produced by voltages applied to deflection plates, or by magnetic fields produced by electric currents passing through deflection coils.

Means are almost always provided for producing two independent deflections of the beam at right angles to one another. When the beam of electrons strikes the screen covering the inner face of the tube, the impact of the electrons excites the luminescent material there and causes it to emit light.

Thus the CRT screen instantaneously displays a single small spot of light whose position depends on the deflecting voltages or currents effective at that instant. Because of the very small mass of an electron and the consequent small inertia of the electron beam, the spot can be deflected at very great rates of speed. "Writing speeds" (that is, speeds of CRT spot motion) of as much as 200 in. per microsecond were used in laboratory test equipment during World War II. Writing speeds of 1/10 in. per microsecond were common in service radar equipment. Not only the position of the spot but also its intensity can be controlled electrically.

The voltage applied to a "control grid" in the electron gun determines the electron beam current to which the light intensity produced at the screen is proportional.

A simple way to display radar signals is in the form of a "one-dimensional" display. The signal beam of the CRT is swept across the face of the tube from left to right at a uniform rate of speed, beginning at the instant a pulse is sent out from the radar transmitter. Thus the distance the beam has traveled to the right from its initial position is a measure of the time that has elapsed after the transmission of the pulse, and the distance of an echo signal from the left end of the sweep is proportional to the range of the target causing the echo. The output signals of the radar receiver are applied to deflect the beam vertically, so that an echo

appears as an upward deflection of the trace. To make sure that the weakest signals that are detectable at all are not missed, the over-all amplification of the receiver is great enough so that random electrical disturbances, called "noise," originating in the receiver, can be seen on the display. For example, in successful attempts to receive a radar echo from the moon, time exposures were taken of the CRT screen. The photograph showed the entire path traced by the spot of light on the CRT face, in this case, in $2\frac{1}{2}$ sec.

On the left could be seen the "tail" of the transmitted pulse leaking into the receiver, and, on the right, the echo signals from the target. The distance of the echo signals from the left side of the CRT screen gave the distance of the target, the moon, as about 250,000 mi.

The type of indicator just described has come to be called an A-scope. Besides being simple, it affords an easy and straightforward way of measuring range.

It makes no use of alterations in the intensity of the CRT spot.

In addition to finding target range, it is usually necessary to determine also the direction in which each target lies as viewed from the radar station. This could be done, in principle, by triangulation, using two or more simultaneous range readings on the same target as seen from separate radar stations. From the standpoint of simplicity, it is far preferable to measure both range and direction from a single radar station.

This is possible if the radio energy sent out from the radar can be confined to a narrow beam, like that of a searchlight. Echoes will then be received only from targets which lie in the direction in which the beam is pointing. If the radar beam is swept or scanned around the horizon, the strongest echo will be received from each target when the beam is pointing directly toward it, weaker echoes when the beam points a little to one side or the other of the target and no echo at all when the beam points in other directions. The bearing of a target can thus be determined by noting the direction in which the radar beam must be pointed to give the strongest signals from that target.

This can be done in several ways, some of which are highly precise. None is more graphic than the radar display called PPI, for plan position indicator. The PPI shows the range and angular disposition of all targets seen by a radar set which is scanning the horizon. In the PPI, the radar echo signals from the receiver are applied to the control grid of the CRT indicator tube in such a way that the screen will be dark in the absence of a signal, and a bright spot will appear when a signal is received.

The electron beam executes a sweep of uniform speed beginning at the instant each pulse is transmitted, just as in the A-scope, but in the PPI each of these sweeps commences at the centre of the tube and goes radially outward. Target bearing is indicated on the PPI by making the direction of each radial sweep on the indicator correspond to the geographical direction in which the antenna (and hence the radar beam) is pointing at that moment. North can be chosen to be at the top of the tube, for example; when the radar beam is pointing north, the radial sweep is executed from the centre upward. When the antenna has swung around to point east, the sweep on the PPI will take place from the centre to the right, and so on. The result is a map, on which the direction of each luminous spot marking a radar echo, measured from the centre of the tube, shows the

bearing of the target causing the echo, and the distance of the spot from the centre of the tube face shows the target range.

In addition to the A-scope and the PPI, many other forms of radar indicator have been devised for special purposes; some of these will be referred to later.

The Basic Radar Set.—A radar set is shown schematically in fig. 2, separated into the major components fundamental to its action. The operation of these components is as follows.

A cycle of operation is begun by the modulator, which applies a high-power, high-voltage pulse to the magnetron, a type of transmitting tube developed specifically for radar use. For the brief duration of the modulator pulse, which may typically be one microsecond, the magnetron oscillates at a frequency of several thousand megacycles per second¹, usually abbreviated simply as mc., transforming the D.C. power applied to it by the modulator into RF (radio frequency) power with an efficiency usually larger than 50%. The RF pulse thus produced travels down the RF transmission line shown by double lines in fig. 2, and passes through the two switches marked TR and ATR. These are gas-discharge devices in which the discharge is initiated and maintained by the high-power RF pulse produced by the magnetron. During this time, the TR (transmit-receive) switch connects the transmitter RF line to the antenna, and disconnects the mixer and the rest of the receiver, in order to prevent damage to these sensitive circuits by the high outgoing power. The ATR (anti-TR) switch, when operated, simply permits the RF pulse from the magnetron to pass through it with negligible loss. Between pulses, when these gas-discharge switches are in a quiescent state, the TR switch connects the mixer to the antenna, and the ATR disconnects the magnetron to prevent any of the feeble received signals from being lost.

The RF pulse, after passing through these two switches, travels down the RF line to the antenna, where it is radiated. As is usual in radar, a single antenna is indicated in fig. 2 as being used both for transmitting and receiving; this requirement gives rise to the need for the duplexing arrangements involving the TR and ATR switches. The antenna design depends on the shape of radar beam required to meet the functional demands placed on the radar. It is almost always mounted on a scanner arranged to sweep the beam through space in the manner desired; simple azimuth rotation is indicated in fig. 2.

After the pulse has been transmitted, the discharges in the TR and ATR switches cease and the system is ready to receive echoes. These are picked up by the antenna and sent down the RF line to the mixer. The mixer shown is identical with the usual mixer of a superheterodyne radio receiver; it is a non-linear device which, in addition to receiving the signals from the antenna, receives power from a CW (continuous-wave) local oscillator operating at a frequency only a few tens of megacycles away from the frequency of the radar transmitter. The difference frequency that results from mixing the echoes with the local oscillator signals contains the same intelligence as did the original echoes, but it is at a sufficiently low frequency (typically 30 mc.)

¹The electromagnetic waves used in radar, like light and radio waves, can be characterized either by their wave length, λ , or by their frequency, ν . These two quantities are related, since their product is the velocity of propagation of light, c ,

$$\lambda \nu = c$$

Numerically, a wave length of 10 cm. corresponds to a frequency of about 3×10^9 cycles per second, or 3,000 mc. per second.

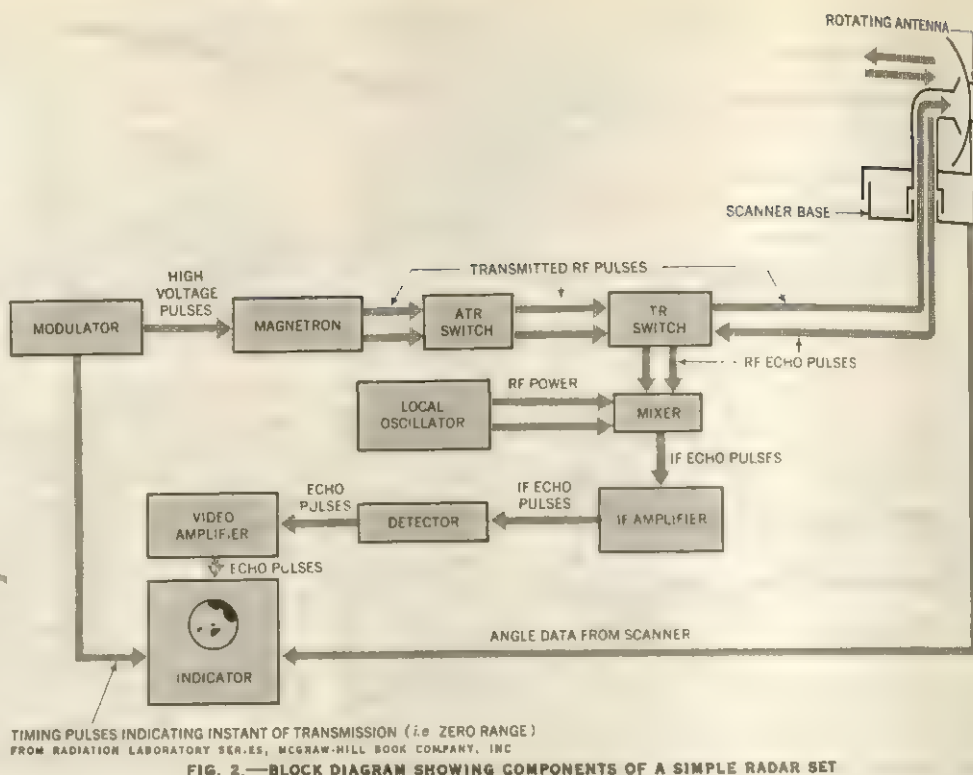

FIG. 2.—BLOCK DIAGRAM SHOWING COMPONENTS OF A SIMPLE RADAR SET

to be amplified by more or less conventional techniques in the intermediate frequency (IF) amplifier shown. Output signals from the IF amplifier are demodulated by a detector, and the resulting unipolar signals, still containing the echo intelligence, are further amplified by a video-frequency amplifier similar to those familiar in television receiver technique.

Output video signals are passed to the indicator for display. The indicator shown is a PPI which must, in addition to receiving echo signals from the indicator, receive a timing pulse from the modulator to indicate the instant for the start of each sweep. It must also receive information from the scanner on the direction in which the antenna is pointing, in order that the radial range sweep be executed in the proper direction from the centre of the tube. The necessary connections are indicated in fig. 2.

Each of the components shown in fig. 2 presented a series of difficult new problems of design during the period of radar development in the years 1935-45. Broad problems of component design are treated later in this article.

II. THE DEVELOPMENT OF RADAR

1. Early History.—Radar was developed independently and nearly at the same time in the United States, England, Germany and France during the 1930s under various names, such as radio detection or radio location. In 1942 the U.S. Navy coined the term radar which became universal in all later applications.

The independent occurrence of almost simultaneous and very similar radar developments in all these countries should not be surprising. The ideas basic to radar principles had been repeatedly presented for many years preceding the development of radar. It is perhaps more surprising that practical radar systems were not evolved at an earlier date.

Of the two ideas basic to pulse radar, the echo principle and the pulse principle, the former dates from the pioneer work of Heinrich R. Hertz in electromagnetic waves. This German physicist in the 1880s, seeking demonstrable proof of theories on the nature of light and radiation that the English mathematician James C. Maxwell had published in the 1870s, produced radio waves in the laboratory. Hertz also demonstrated that these radiations could be reflected by metallic objects, as light is reflected by a mirror.

While Marchese Guglielmo Marconi and others at once pursued the radio communications possibilities that Hertz had opened up, a German engineer, Christian Hülsmeyer, developed a simple

form of radar, or radio echo device, to prevent ship collisions. He even obtained patents in 1904 in several countries. But there was little interest in such a device at that time.

Meanwhile, the radio echo or reflection phenomenon was repeatedly observed, and comments were often made regarding its possible uses. Nikola Tesla wrote in *Century Magazine* (June 1900, lx, p. 208) that by means of radio a moving object such as a ship at sea might be detected and located. Marconi, speaking in New York city at a meeting of the Institute of Radio Engineers in 1922, elaborated upon this same application.

By the mid-1920s radio researchers were seeking to measure the height of the ionosphere, a layer of ionized gas near the top of the atmosphere that reflects high-frequency radio waves, making possible long-range radio transmission around the curve of the earth. In England, under the auspices of the British Radio Research board, Edward V. Appleton and Miles A. F. Barnett employed CW radiations in original experiments beginning in 1924 to determine the altitude of this reflecting layer. The method they used involved observation of the interference effect between the waves reflected from the ionized layer and the direct (or ground) waves radiated by the transmitter.

The second idea basic to radar is the pulse principle, which was developed in 1925 by Gregory Breit and Merle A. Tuve of the Carnegie institution, Washington, D.C., in ionospheric work. Their pulse-ranging method was soon adopted by ionospheric investigators all over the world.

2. Development Before World War II.—In the 1930s radio detection research began to receive earnest attention in a number of countries, largely under military supervision and in secret, because of the urgent need to detect and locate enemy warplanes at night or in cloud.

Germany.—German scientists, having begun development of a ship detector for the navy as early as 1933, soon concentrated their efforts on aircraft detectors. By Sept. 1939 a German ground set, the Freya, for early warning of approaching airplanes, was in production. The ship detector Seetakt went into production soon after. An especially excellent radar, the Würzburg, its medium-length waves of 50 cm. (at 600 mc.) giving sufficient accuracy to direct effective antiaircraft fire against unseen planes, began to be employed in mid-1940 before any comparable precision position finder or gun layer (GL) radar had been developed by the Allies.

France.—The French, who had developed a simple obstacle warning set (an iceberg detector) for use aboard the ocean liner "Normandie" in the mid-1930s, also devised an aircraft warning system just before World War II. This was an interference-type radar using long waves (at 30 mc.) and requiring wide separation of the transmitter and receiver. The system was developed by Pierre David, chief engineer of the National Radio laboratories, who worked in great secrecy with army officers and civilian technicians. Not until about the time of an exchange of radar information with the British in 1939 did the French begin serious work on high-power pulse radar.

United States.—Scientists under A. Hoyt Taylor and Leo C. Young in the Naval Research laboratory and under Col. William R. Blair in the Army's Signal Corps laboratories made early progress in radio detection. Navy workers had devised an interference type of radio detector by 1930. Army scientists first worked on microwave radar types in the early 1930s, but the sets were failures militarily because they could not attain sufficient range. The output power of microwave oscillator tubes at that time was too weak.

Success came by 1936 when both the army and navy developed pulse radars on longer wave lengths generated by special high-power tubes. The signal corps demonstrated a model of the army's first radar, a searchlight control (SLC) set, in May 1937. This set was developed for the coast artillery corps to locate in darkness any airplane within searchlight range so that gun crews could trap the plane in searchlight beams and direct visual fire upon it.

The army air corps at once put in a priority request for a long-range aircraft detector for early warning (EW). This led to the development of a mobile set capable of detecting and locating air-

craft well over 100 mi. distant. The signal corps completed development of both this set and a fixed version by the end of 1939, and contracts for their production were let by 1940. Both were in military use before the Pearl Harbor attack. U.S. navy radars were also in production and use by then, following successful ship-board tests in early 1939.

Great Britain.—British radar grew from the efforts of a committee that the air ministry set up in 1934 for the scientific survey of air defense. This committee received, among other suggestions, a carefully worked out plan for the radio pulse-echo detection of aircraft. This was tested on Feb. 26, 1935, by a physicist then heading the radio department of the National Physical laboratory, Robert Watson-Watt.

The first experimental system of the type proposed by Watson-Watt was set up in the late spring of 1935 on the east coast of England. By that autumn the main features of a chain of warning stations to protect England had been worked out. By early 1938 the first five chain home (CH) stations, which protected the Thames estuary, were completed and in operation under Royal Air Force personnel. A chain of similar stations was erected around the borders of Great Britain in succeeding years.

Development emphasis then shifted to air-borne radar equipment. Two types were designed: (1) a set for the detection

BRITISH CROWN COPYRIGHT RESERVED REPRODUCED BY PERMISSION OF HER BRITANNIC MAJESTY'S STATIONERY OFFICE

WOODEN RECEIVING-ANTENNA MASTS OF THE EARLIEST BRITISH RADAR, THE CH. THESE SETS WERE USED THROUGHOUT WORLD WAR II, HAVING BEEN USED IN 1944-45 TO DETECT GERMAN V-2 ROCKETS DIRECTED AT LONDON. SET SHOWN IS AT SWINGATE, DOVER, FACING ACROSS THE ENGLISH CHANNEL TOWARD FRANCE

of surface vessels or surfaced submarines by patrol aircraft (called ASV, for air-to-surface vessel), and (2) an equipment to enable night fighters to home on enemy aircraft (called AI, for aircraft interception).

An experimental ASV system was successfully demonstrated during British fleet maneuvers in Sept. 1938. Experimental AI equipment was demonstrated to the chief of R.A.F. fighter command in Aug. 1939.

The focusing of radar energy into sharp beams is especially important in the case of air-borne radar; for energy reflected when the radar beam strikes the ground or sea beneath the plane can mask entirely the much weaker echoes of the targets sought. Sharp beams can be obtained by the use of either very large antennas or very short radio wave lengths. Since large antennas cannot be carried in aircraft, short wave lengths are essential. The early British interest in military air-borne radar led to an intensive search for a type of radio transmitter which could give very high-power pulses at wave lengths of a few centimetres.

By early 1940, British researchers succeeded in developing just such a transmitting tube, the revolutionary multicavity magnetron,

which gave about ten kilowatts of pulse power. The invention of this tube made microwave radar practical for the first time, and the history of modern radar can be said to date from the introduction of this device.

3. World War II Radar Development.—By the end of 1940 U.S. and British radar work was being carried out on a basis of full mutual exchange of information. A British technical mission, headed by Sir Henry T. Tizard, visited the U.S. in September and October of 1940, bringing complete information on British radar developments and samples of the cavity magnetron. Arrangements were made for continuing exchange of technical information and for co-ordinating the development work of both nations.

In discussions with the microwave committee of the U.S. National Defense Research committee (NDRC), which had been set up a few months before, members of the British mission proposed that the U.S. undertake two specific microwave developments: a microwave AI radar and a microwave position finder or gun layer (GL), for anti-aircraft fire control. To implement these proposals, the microwave committee arranged to create a radar development laboratory staffed principally by university physicists in a pattern originated by the British several years earlier.

United States.—The Radiation laboratory, as the new NDRC establishment was named, opened its doors at the Massachusetts Institute of Technology, Cambridge, Mass., early in Nov. 1940. Its director throughout its 62 months of life was Lee A. DuBridge, on leave from the University of Rochester, later president of California Institute of Technology, Pasadena, Calif. The U.S. army and navy looked to the new Radiation laboratory for the development of microwave radar. Their own development agencies were already fully occupied with the many problems connected with getting the long-wave radar, already developed, through manufacture and into service use. At the end of 1940, the usefulness of microwave radar seemed highly speculative, and the army and navy laboratories quite properly felt it more important to concentrate their effort on radar techniques which had already been worked out.

During 1941, though not a single microwave radar unit was delivered for service use, development work at the Radiation laboratory broadened far beyond the two specific projects which had been suggested by the British mission. Microwave equipment was showing great promise for many different wartime uses, and a considerable amount of army and navy interest was developing.

The tremendous expansion of the radar development program during the war years can be measured by the personnel figures of the various laboratories. The total personnel of the Radiation laboratory was about 40 at the beginning of 1941; by the middle of 1945 it had risen to its peak of nearly 4,000. The radar section of the Naval Research laboratory increased its personnel to about 600 in the same period. The radar section of the Signal Corps laboratories grew into the Evans Signal laboratory, with a peak personnel of more than 3,000. A similar growth took place at the Aircraft Radio laboratory at Wright field, Dayton, Ohio.

Great Britain.—British research and production experience during World War II set a precedent for wartime radar development in the U.S. The Telecommunications Research establishment (TRE), located during the last years of the war at Malvern college, Eng., pioneered the path followed by the Radiation laboratory in the U.S. TRE originated five years earlier than its American counterpart, having begun with a nucleus of dedicated physicists and technicians who built the first CH station on the shore of the North sea in 1935.

By 1945 TRE personnel grew to number about 3,000. Throughout these years British government and military officials co-operated closely with university scientists and industrial engineers, providing funds and facilities while permitting great latitude and free play of imagination to the end that complex but workable equipment might be devised and quickly brought to combat use. A new pattern of military-civilian co-operation and a spirited partnership of civilian scientists and military users was created with marked success, first in England and then in the U.S., bringing revolutionary concepts and weapons to bear upon the enemy with devastating effectiveness and crucial timeliness. Experimental radar devices, hand-built at the laboratories, were often used in

combat missions, the equipment being installed and maintained by civilian technicians who sometimes operated it as well.

The British and U.S. radar efforts together brought against the enemy increasing quantities of superior microwave radar. Notable examples were the precision position finders or GL sets that, by 1944, surpassed the German Würzburg radars. Such too were the efficient air-borne microwave radars whose shorter wave lengths permitted use of smaller antennas and gave greater detail (higher resolution) of target reflections. The first of these was the British H₂S (wave length 9 to 10 cm.), used in 1943 in such effective raids as those on Hamburg. Next was the improved H₂X which employed still shorter waves (about 3 cm. long).

Increasing use of these and other microwave radars replacing long-wave sets such as the enemy continued to employ (for want of efficient microwave generators like the cavity magnetron) gave the Allies through the last two years of the war an overwhelming radar superiority. In particular, the Allies developed jamming devices that blinded all German radars, both ground and air-borne types, that were operating on medium or long waves. Meanwhile, the Allies freely employed their superior microwave sets (unaffected by medium- or long-wave jamming) to direct attacks upon enemy targets at sea, on land and in the air.

Germany.—German radar development during the war was much retarded, as compared with the Allied effort, by over-confidence at first and throughout by poor management and defective co-operation between the military services and civilian scientists. Particularly harmful was a cutback in research that Hitler ordered in 1940. But as Allied air attacks increased, German radar production was stepped up.

More than 2,000 Freyas were built during the war and thousands of other sets as well. Improved Würzburgs and other types were developed and organized into effective systems of early warning, target tracking, and fire control or gun laying. An effective AI set, the Lichtenstein, was hastily devised and placed in night fighters. All these efforts enabled the Germans to take an increasing toll of Allied aircraft over western Europe until a turning point in the radar war came in mid-1943.

When in Feb. 1943 the Germans salvaged an H₂S radar and its magnetron from a plane wreck near Rotterdam, they first learned that the Allies had developed microwave sets. (By the end of 1943 they learned of the still better 3-cm. radar when an H₂X set was recovered from a U.S. bomber that also crashed in Holland.) Desperately, the Germans hastened to set up the Rotterdam commission to develop cavity magnetrons and microwave radars, but only toward the very end of the war did they begin to produce the Berlin series of microwave sets, and these were too late to be of any help.

Japan.—Such radar as the Japanese had developed before World War II was of the continuous-wave type, utilizing interference or Doppler techniques. Not until 1940 did work begin on pulse-type radar.

Some types were strongly influenced by foreign radar design. For example, a Japanese version of the Würzburg was developed by 1945, based on plans the Germans had sent via submarine. The army's Taichi-6 resembled a U.S. army set, and a type of naval ground-based radar for anti-aircraft fire control, the S-3, was based upon another U.S. set, a number of which had been captured in the Philippines in 1942. More than a thousand sets of an ASV type, the Taki-1, were produced. Using waves a metre and a half long, at 200 mc., the set was mounted in Japanese bombers that carried the necessarily large antennas mounted on the exteriors of their fuselages.

The Japanese also developed a 10-cm. magnetron. One of their best shipboard radars employed this type of tube. They did not, however, develop in World War II any radar comparable to the Allied microwave SCR-584 or the MEW (microwave early warning) radar set.

4. Use of Radar in World War II.—The brilliant success of the early British chain home stations in countering the threat of the *Luftwaffe* demonstrated the usefulness of radar in its original military role—the detection and location of aircraft at ranges and under conditions of visibility that precluded locating planes in any

other way. As the war continued, many other uses for radar were developed. The most important are described below.

Aircraft Warning.—The earliest sets used were those of the British home chain. These large installations used radio waves about ten metres in length, and gave their display on an A-scope. Target bearing was found by comparing the intensity of the target signal received on one fixed receiving array with the intensity of the echo from the same target received on another fixed array aimed in a different direction; the elevation angle of a target, and thus its altitude, was measured in a similar way. These CH radar stations, as they were called, remained the principal reliance of the British radar defense throughout the war, and were used in 1944 and 1945 for the detection of German V-2 rockets aimed at England.

Later aircraft warning sets used shorter radio wave lengths, usually about 1.5 to 3 metres. At this wave length, a relatively narrow beam can be produced by an antenna array small enough for installation on shipboard, or for use in a transportable ground equipment. At the same time, the use of a radar beam requires continuous scanning in azimuth in order to cover all directions from the station.

In early 1944, there was introduced a microwave early-warning radar, operating on a wave length of 10 cm., which was highly successful. The radar beam produced by this set was only 1° wide in azimuth; in consequence, the ability of the set to resolve closely spaced targets on its PPI display was very much better than that of earlier equipment having broader beams. In large R.A.F. raids, often comprised of more than 500 individual aircraft, most of the bombers could be seen separately by MEW radar.

In situations of heavy air traffic, or under conditions where precise control of aircraft is important, such high radar resolution is extremely valuable.

Identification Equipment.—When a radar indicator shows echoes from dozens, or even hundreds, of aircraft, it becomes important to know which of these aircraft are friendly and which hostile. This requirement was recognized by the British early in their work on radar, and they devised an identification system, called IFF (identification as friend or foe), which was adopted by the Allied forces during World War II.

All friendly aircraft were equipped with a transponder—a radar beacon (*see below*) which gave a coded response when the aircraft carrying it was in the beam of a radar set. Arrangements were made to display this response on a scope which was either that used by the challenging radar set, or a special scope associated with the radar. Aircraft showing an IFF response were taken to be definitely friendly; aircraft not showing such a response were doubtful. Either they were hostile, or they were friendly planes whose transponders were out of order or not turned on.

While IFF was extremely useful in the early days of the war when aircraft density was still low, it failed operationally in the enormously high aircraft densities of the latter years of the war. A means for rapid and secure identification was, therefore, one of the unsolved operational problems of radar at the end of World War II.

IFF equipment of the standard type was also used by Allied naval vessels in order to identify friendly ships both to aircraft and to other surface vessels. In this use, of course, the problem of high density seldom arose, and maintenance of transponders was easier than it was in aircraft. IFF in ships was, therefore, considerably more reliable than it was in aircraft.

Control of Aircraft Interception.—The observation was early made by the British that, since both a hostile plane and a friendly fighter can be seen on the indicator of a single radar, it might be possible for a ground controller, viewing the radar scope, to coach the fighter into position to make an interception. The development of the plan position indicator greatly facilitated such ground control of interception.

Special radar equipment, called GCI, was designed for this purpose in the earliest days of the war, and proved to be quite successful.

When the Germans abandoned daytime attacks on England

at the end of 1940, the technique of ground control became much more exacting. It was no longer sufficient to bring the defensive fighters into the general vicinity of the enemy aircraft and then to rely on the pilot's vision to complete the interception. A skillful ground controller could, under favourable circumstances, bring a fighter close enough to his target to enable a visual contact to be made even at night; but this was so difficult that further radar aids to the interception were clearly needed.

AI Radar.—It was this reasoning which led to the development of radar for aircraft interception. Night fighters were provided with air-borne radar sets with a range of a few miles against other aircraft. The ground controller coached the night fighter into a position a mile or two behind the hostile plane, a little below and on the same course. He then instructed the radar observer in the night fighter to turn on his AI equipment. If the early phases of the interception had been successfully carried out, the hostile aircraft gave a signal on the AI radar, and the combat was joined on the basis of homing information made available by the night fighter's own radar.

By the time reliable microwave AI equipment had been developed by the Allies in World War II, they enjoyed such thorough air superiority that it did not play a major tactical role. The early British 1.5 metre AI equipment used in 1940 and 1941 had many drawbacks, but it was sufficiently effective to enable the R.A.F. to master the night-bombing campaign of the *Luftwaffe*.

Antiaircraft Position Finders or Gun Layers (GL).—The earliest radar set developed by the U.S. army signal corps was the searchlight control set, mentioned above, for determining azimuth, elevation and range of aircraft targets at night in order to direct searchlight beams upon them. These sets also were employed for control and direction of gunfire under conditions preventing visual tracking—at night or in cloud—although the set had not been designed for GL use. Such use of radar for fire control became a most important application in World War II, but neither early British nor U.S. sets, working at wave lengths of a metre or more, had sufficient accuracy to direct very effective blind gunfire.

The introduction of microwave sets, however, enabled the design of radar position finders whose accuracy was good enough to permit blind fire that was as effective as visually controlled fire. The most successful of all Allied types of such equipment was the SCR-584. This U.S. radar measured the azimuth and elevation angles of a target with an error of less than one-twentieth degree, and range with an error less than 25 yd. It was the first radar equipment which incorporated automatic tracking; when the SCR-584 was pointed at a target, it could be "locked on" in such a way that servomechanisms actuated by the radar kept its antenna pointing continuously at that target.

Naval antiaircraft fire was controlled by radar of a similar sort, although no navy, Allied or Axis, had equipment for the purpose that was as effective or as satisfactory as the U.S. army's SCR-584.

Close Control of Aircraft.—The GCI techniques which were referred to above had as their aim the location of a friendly fighter in such a position that he could attack a hostile bomber, usually with the help of an AI radar carried by the night fighter. Minor errors in positioning the friendly plane were usually relatively unimportant, and the target with respect to which the friendly plane was being positioned was an aircraft moving with a speed comparable with that of the plane under radar control. Both these facts simplified the GCI problem.

As the position-finding precision of radar grew, it began to be clear that a ground controller could direct aircraft accurately into a desired position with relation to ground targets. Two principal problems presented themselves during the war, one of which is important in peacetime air operations.

First, the tactical air commands that accompanied the U.S. armies on the continent of Europe were composed, for the most part, of fighter bombers. These single-seat aircraft were much too small to carry radar equipment, and the pilot of such a plane was much too busy to interpret its readings even if he had had radar. Nevertheless, the TAC aircraft had to operate often in conditions of greatly restricted visibility. Controllers located at

ground radar sets had considerable success in guiding TAC fighter bombers to their targets by radiotelephone instructions. Even entirely blind bombing was done by such aircraft, altogether on the basis of course and release-time instructions received from a controller at a ground radar. The SCR-584, suitably modified, was used for this work.

The second application of close aircraft control from the ground is that of coaching a plane in to a landing under poor visibility conditions. A special high-precision radar set, called GCA (ground controlled approach), was designed at the Radiation laboratory for this purpose. Though it emerged from production rather late in World War II, it was used quite successfully both in Europe and in the Pacific. Its use had become common by the 1960s in both civil and military air operations.

Surface Search and Fire Control.—In addition to locating aircraft and directing fire against them, radar was used during the war to locate and direct fire against surface vessels, both from other ships and from coastal defense stations. As will be seen in the next section, microwaves enjoy a great superiority in search for targets near the surface of the sea, so that it often happened that the same radar was used for search and for fire control against surface vessels.

Such radar could also locate precisely the splashes caused by the fall of shot, thus permitting the spot correction of unseen fire. In naval engagements in the Pacific, on several occasions, ships of the U.S. fleet engaged and sank Japanese vessels without ever seeing them visually.

ASV Radar.—Of the several types of air-borne radar equipment used in the war, that employed by patrol aircraft for searching out and attacking surface vessels was one of the most common. A ship on the open sea is an ideal radar target, and even quite primitive equipment suffices to home on such an object. As the art of radar design advanced, ASV equipment developed from a heavy, bulky installation to a compact and effective unit.

ASV radar was most effective in the antisubmarine campaign. During much of 1943, German submarines were sunk at a rate not far from one per day, two-thirds of them by aircraft attack. Almost all of the aircraft attacks developed from radar sightings.

Means were also developed for bombing ship targets accurately on the basis of the radar display. In a single month, a single squadron of the U.S. 14th air force sank 110,000 tons of Japanese shipping in the China sea, entirely at night and entirely by radar.

Air-borne Radar for Navigation and Bombing.—During trials of AI and ASV radar, it was found that microwave equipment, with its narrow beams, could give a sufficiently good picture of the terrain beneath an aircraft to enable navigation by pilotage. Cities and built-up areas returned much stronger signals than open country, and hills, rivers and coast lines were especially well defined.

The British R.A.F. bomber command pioneered in using such radar to guide its pathfinder aircraft. These planes, manned by specially chosen personnel, dropped flares on the target at which the main force aimed by ordinary optical means. The U.S. strategic air forces, committed to daytime bombing, found by experience that target visibility was often so poor that in order to maintain full operation they also needed such radar aids.

Even on occasions when target visibility was good, the radar was useful in permitting the bombers to line up correctly on their approach to the bombing run. A medium-sized city is visible for about 50 miles on radar of wartime performance; it can rarely be seen as far as this with the eye. Of the 400,000 tons of bombs dropped by the 8th air force after Nov. 1943, when this equipment (called "Mickey" or "H₂S") was introduced, more than half was aimed entirely by radar.

Beacon Bombing Systems.—Mention has already been made of the use of radar beacons for identification. Since these beacons give an immediate response to a radar challenge, they provide an excellent means for measuring the range to a point whose nature is known. Two such measurements based on a single point enable the exact position of such a point to be found by triangulation.

Since range can be measured so conveniently and so accurately by pulse-timing methods, every precise position can be determined.

Two different bombing systems were based on this principle during World War II. In one of them, called "Oboe," the aircraft carried a radar beacon. The beacon was challenged by two ground stations, and the range of the aircraft from each station measured. Signals were sent to the plane by radio to keep it on a circular course of constant range from one station, called the "cat." The other station, called the "mouse," sent signals to the aircraft indicating the exact moment of bomb release necessary to hit the previously chosen target.

The Oboe system was highly accurate; with good ground and air crews the operational errors were less than 250 yd. from an altitude of 30,000 ft. Its limitations were that, since it depended on the ability of ground stations to see the signals from a beacon in the bombing aircraft, it would not work over the optical horizon (about 250 mi. for an altitude of 30,000 ft.); and that it demanded a high degree of co-ordination between two widely separated ground stations. Even with this co-ordination, it could handle only one aircraft at a time.

Despite the limitations of the Oboe system, the British used it quite successfully to guide the pathfinder aircraft of R.A.F. bomber command. The devastation of the Ruhr, which was just within Oboe range from the United Kingdom, was carried out almost entirely with the help of Oboe.

In the other type of beacon bombing system, called "H" by the British, beacons were placed on the ground at accurately located spots, and the interrogation and display equipment was carried in the bombing aircraft. A U.S. system based on this principle, called Shoran (for short range navigation), was highly successful during World War II.

Although Shoran was subject to the same horizon limitation as that affecting Oboe, it did not suffer from as severe a limitation in traffic-handling capacity. Each aircraft could challenge the ground beacons independently of all the other planes that might be doing so at the same time. It was with Shoran that the error in the map position of Corsica, already mentioned, was discovered.

Electronic Navigation Systems.—The beacon bombing systems and the air-borne radar for navigation that have just been described will be recognized as navigational equipment. They were rather specialized in nature, being designed for the exacting use of leading a bomber to its target. No such accuracy is needed to facilitate the ordinary navigation of aircraft from base to base. Radio-beam navigational aids to such navigation had been in use for years, but the development of pulse-timing methods for radar led to the development of navigational aids based on the pulse-ranging principle. Among the more important systems of this sort are the British Gee and the U.S. Loran.

Air-borne Range-finding and Gun-laying Radar.—The vigorous opposition of German fighters to Allied bombing in the early days of World War II led to the U.S. development of light, compact radar to aid in air-to-air gunnery, intended principally to contribute to bomber defense. One type was an automatic radar range finder for optically aimed fire by daylight. Another provided complete position-finding to protect bombers against night fighters under conditions precluding optical sighting. Both of these radars became available during World War II, but at such a late date that their operational usefulness was small. In the Korean War, however, they and successor equipment proved indispensable aids to air-to-air gunnery in jet aircraft combat.

Radar Countermeasures.—Use of radar by the Germans and the Japanese led to a considerable Allied effort in the field of countermeasures designed to mislead enemy radar or to render it ineffective. A similar effort was mounted by the Germans and the Japanese. These countermeasures took two forms: they consisted either of electronic "jamming" or "spoofing" of enemy radar by the transmission of suitably timed signals on the appropriate frequency; or, alternatively, they involved the dispersal of material which gave confusing radar reflections and thus hid attacking aircraft.

The second type of radar countermeasure was the most im-

important single means of confusing enemy radar. Aluminum foil, cut into strips about a half wave length long at the enemy radar frequency, was the most commonly used form of material dispersed from aircraft to give false echoes. Such material was called "window" by the British, "chaff" by the U.S. army air force, and *Dieppel* by the Germans. Long-wave radar, with its broad beams, was the most readily confused by this means. The appearance on the scope of an Allied 10-cm. radar of "window" cut to confuse the German 60-cm. radar showed false echoes which were prominent but not hopelessly confusing. German radar, however, could see the aircraft targets under these conditions only with the greatest difficulty.

For about 18 months, both the Germans and the British refrained from using this deceptive trick, on the theory that the other side was ignorant of the possibility of doing it. Once it was introduced, however, the R.A.F. bomber command dispensed in the form of window, on each full-scale raid, a weight of aluminum sufficient to construct three heavy bombers. Loss figures showed that the protection afforded by this amount of window saved, on the average, seven bombers per raid.

5. Radar Development After World War II.—At the close of World War II the main outlines of radar system design had been reasonably well defined, and many of the operational applications had been completed. In the following years radar development included improvements of components and circuitry, electronic processing of received data, increasing use of solid-state transistors and masers, introduction of genuinely new components such as ferrite duplexers and new scanning methods, both mentioned below, and many new applications.

In civil uses commercial aviation and marine vessels increasingly employed radar aids to navigation. Highway police used a simple form of CW for the detection of speeding vehicles, the Doppler shift of the reflections from moving cars enabling instant and direct measurement of their speed. Astronomers and space researchers found that radar could help map the moon and could yield usable echoes from the sun and planets.

In U.S. military uses, remarkable attainments in transmitters of ever higher power and in receivers of greater sensitivity led to extremely long-range radars for early warning of ballistic missiles. Pulse-Doppler (PD) methods, utilizing such refinements as data processing and "memory" circuits, enabled the development of supersensitive radars for use in ground surveillance and personnel detection.

Military Developments.—Military radar equipment, as such, underwent little improvement in the period between the end of World War II and the beginning of hostilities in Korea in 1950. The Korean conflict made greatly increased military budgets available, but even then only detailed improvements in radar performance took place, resulting mainly from the development of improved components. This is well illustrated by the fact that radar sets differing only slightly from the SCR-584 (development of which was undertaken in 1941 with field use beginning in early 1944) were built for equipping the NATO military forces in the mid-1950s.

The most prominent postwar trend in the design of military radar systems was toward the elimination of human beings as links between a radar indicator and the controls of a weapon system. This general development was forced on military technologists by the astounding increase in aircraft performance, the development of nuclear weapons, the appearance of successful guided missiles and by the growth of commercial aviation.

In the years following World War II, the development of jet engines tripled the speeds of relatively conventional aircraft, thus putting unprecedented demands on air warning and control organizations and on air defense generally. The leisurely human plotting-and-telling organizations of World War II clearly had to be replaced by something faster and less fallible. If anti-aircraft guns were to be useful at all, they would clearly have to be controlled entirely automatically to engage such high-speed targets. The performance of fighter interceptors had increased to the point where the reflexes of a human pilot were barely adequate to control an attack; a high degree of automatic control extending from

the AI radar to the final weapon—gun or rocket—was clearly required for the best results.

In the case of guided missiles, the situation was even plainer. An interceptor missile is a fighter aircraft without a human pilot. There can be no debate about the requirement for automatic control. The same is true of long-range missiles intended for a strategic bombing role, and indeed for missiles in general. In all these cases, radar is an important part of the system as a whole.

In addition, the development of nuclear weapons, to the point at which a single well-executed air raid might utterly destroy the capability of a great country to wage war, made it imperative to have an air-defense system that would be continuously alert and effective against a single unexpected raid. At the same time, the vast growth of civil aviation translated this requirement into the need for developing a system which could keep current track of thousands of aircraft, so that potentially hostile aircraft could be distinguished and investigated (counterattacked, if necessary) before they had an opportunity to attack. Any such system obviously would require a degree of automatic operation not dreamed of during World War II.

Fortunately, the development of high-speed digital computers, begun in the late years of the war, provided the basic techniques which made it possible to mechanize the use of radar data. The most ambitious undertaking of this sort in the 1950s was the development of the semiautomatic ground environment (Sage) system, designed to control weapons defending the continental United States against air raids.

In the Sage system, high-performance ground radar sets were placed in the U.S. and Canada at locations that gave reasonably continuous coverage of aircraft, except those at very low altitude. Signals from these radars were transmitted to central control stations, each equipped with a vast computer capable of establishing and maintaining aircraft flight paths from the intermittent radar data, performing partial identification of aircraft from flight-plan information filed by friendly aircraft before take-off, assisting in the assignment of defensive fighters to investigate unknown aircraft, and doing the GCI job for fighters and interceptor missiles ordered to the attack. In addition, such defense organizations as naval units and the anti-aircraft missile batteries guarding important targets could be alerted and given information on the tracks of incoming hostile aircraft.

To increase the time available to ready defenses, long-range radar installations (the distant-early-warning, or DEW, line of radars) were constructed in the far north of the North American continent. Man-made islands (Texas towers) were built on the eastern continental shelf as far out as 200 mi. into the Atlantic. Ultra-long-range aircraft equipped with high-performance radar were flown as air-borne pickets as far out as 1,000 mi. at sea.

The DEW line was designed to detect and locate aircraft while they were yet a considerable flight time distant, even at supersonic speeds. But against much swifter long-range ballistic missiles, which began to present a threat by the mid-1950s, another radar system had to be developed. Called the ballistic missile early warning system, or BMEWS, this comprised two stations in North America and one in northern England.

The first BMEWS station, which began operation in Oct. 1960 at Thule, Greenland, under U.S. air force direction, cost nearly \$500,000,000. Four antenna arrays, each standing 165 ft. high and 400 ft. long, were designed to emit the highest power radiations employed up to that time in military radar. The immensely powerful transmitters, generating several million watts at peak pulse, projected two fanlike beams over the north pole and far beyond, capable of detecting a missile 3,000 mi. distant when it attained an altitude of 600 mi. Two sets of echo data, which would be received as the missile passed first through the lower beam and then through the upper one, would enable electronic calculators at Thule to predict within moments the missile's course and impact area. Thus about 15 or 20 minutes could be provided for warning and countermissile action.

During the late 1950s there were many military applications of radar besides the advanced warning and interception efforts described above. Marked progress was made in radar range and

accuracy. A variety of new applications appeared. Unprecedented demands for both offense and defense uses arose from the needs of military technology in support of radically new concepts of modern armed forces in the atomic and missile era. The needs and the applications involved navigation, meteorology, bombing, mapping, missile tracking and guidance, reconnaissance and surveillance.

Combat surveillance, to illustrate only one application, resulted in U.S. army requirements for radar able to detect and locate such moving targets as a creeping soldier at short ranges and moving vehicles and troops at longer distances. The need for such "intrusion detectors" led to radar systems that combined certain characteristics of both pulse and CW techniques. The consequence became a type of radar system called pulse-Doppler, or PD, discussed near the end of this article.

Several types of PD radar, for detection and location of moving targets only, were developed for sensory and surveillance uses by ground troops. A small portable set called the "silent sentry," which used transistors instead of electron tubes and could therefore be readily powered by batteries, was able to detect moving tanks, trucks or troops up to 3 mi. distant, converting the pulse-Doppler echoes into audible sounds in the earphones of the radar operator. Differences in the sound made it possible to distinguish a walking from a running man up to a half mile away. Target location could be determined with an error of less than 25 yd.

A larger medium-range system indicated moving echoes, both audibly in headphones and visually on an oscilloscope, with a sensitivity so great that the audible signals differed recognizably for tanks, trucks or troops up to 10 mi. distant, and for a creeping man up to 2 mi. away.

Military needs for detailed surveillance of large areas of enemy terrain under conditions of cloud or night (preventing normal photography) and at considerable distances from one side (safely within friendly territory) led to a remarkable air and ground radar system developed by University of Michigan scientists and the U.S. army signal corps. The echo signals of the air-borne radar are recorded on film during the surveillance flight. This film is developed after the plane lands and is then processed by an analogue computer. The process yields a detailed presentation of the scanned area, which appears as if it had been viewed directly beneath the airplane, although actually it lay miles to one side. The entire system thus departs radically in its signal storage and delayed output aspects from radars that give an instant visual or aural indication of targets. The system also embodies a major innovation in its unique antenna treatment. Fine radar focusing and resolution, revealing great detail at long distances as well as in the foreground, would ordinarily require an immensely wide antenna, obviously impossible to mount in an airplane.

Yet the superior effects of such a huge antenna array are attained with a 5-ft. antenna (the size that is actually employed) by coupling its action to the forward flight of the plane. The forward motion, combined with the recorded reception of echo pulses and subsequent treatment in a computer, permits a scanning and focusing effect as though the short antenna were extended many times the length of the airplane. This circumstance requires exact navigation and automatic correction of inevitable flight aberrations. Therefore, a flight navigation system, including an automatic pilot, is included in the system design. As a result the radar is kept in accurate focus throughout the surveillance flight and is focused simultaneously at all ranges. The printed product turned out by the computer resembles a photographic map with better detail at greater ranges than previously possible—revealing, for example, the individual poles of a telephone line seen almost lengthwise many miles away.

Civil Developments.—Immediately after World War II several manufacturers in Great Britain and the U.S. offered simple radar equipment suitable for coastwise navigation. Ship-borne sets generally employ microwaves in the X band (3 cm.) in order to keep the antenna size small. The rotating antenna presents upon a PPI scope the echoes from the coast lines, obstacles and other ships. Shipboard radars steadily increased in number, coming into use even in small fishing and pleasure craft.

In some ports large radar surveillance sets have been installed ashore overlooking the harbour and approach waters in order to assist shipping when visibility is bad. The radar operator observing ship movements in the confined waters advises pilots of harbour traffic conditions from moment to moment by means of radio-telephone. A notable system at Liverpool, Eng., installed in 1948, guided ships through the narrow approach waters under adverse conditions of visibility. The system utilized six PPI scopes to cover in detail (discriminating within 40 yd.) the 14 mi. of the Mersey river channel and harbour front that are kept under constant surveillance.

Proposals were also made soon after World War II for the installation of radar navigational equipment in commercial airliners and for the establishment of ground radar stations along commercial airways and at airports. The U.S. Civil Aeronautics administration, which became the Federal Aviation agency (FAA) in 1958, promoted installation at major airports of GCA radar systems by means of which traffic controllers could observe airliners approaching in bad visibility or at night, guide them by means of radio-telephone and "talk" the pilots safely down to the field. GCA had not been provided at all airports in the early 1960s, partly because pilots preferred the instrument landing system, or ILS, a radio navigation and landing aid that has long been standard equipment at many airports over the world.

GCA in this application requires two types of radar. Airport surveillance radar (ASR) scans a circle 30 mi. or more in radius around the field and displays upon a PPI scope in the control tower all aircraft within range up to within about 5 mi. Within this smaller inner circle a precision approach radar (PAR) takes over, using a limited-angle PPI or B-scope and a range-height indicator. Airport surveillance sets employ pulse modulation, and all recent types also include MTI so that operators can switch to the MTI technique if necessary in order to distinguish moving echoes (airplanes) from fixed reflections in the area being scanned.

More GCA radar of an improved type was coming into use by the early 1960s as the FAA carried out a program of installing sets with longer range and greater refinement. A high-definition radar, known as airport surface detection equipment (ASDE), that gives almost photographic clarity (using very short 1-cm. waves) in distinguishing planes and motor trucks on the field, began to be used in 1960. The first two installations were made at the Idlewild, N.Y., and Newark, N.J., airports.

Meanwhile, air-borne radars, using wave lengths of about 5 cm., were being installed in increasing numbers of large modern air transports, primarily for storm detection, enabling pilots to fly evasive courses around dangerous turbulence. Frequencies corresponding to the wave lengths of about 5 cm. were found to be best for echo reflection from storm clouds.

Radar astronomy, the study (by means of radio reflection) of the moon and other bodies in the solar system, became possible with increased transmitter power, greater receiver sensitivity and the uses of electronic computers to discriminate the extremely weak echo signals from the stronger interfering signals of inevitable noise. The radar technique enables more accurate measurement of distance than optical methods permit, and it enables study of surface structure of bodies in the solar system. Radar astronomy is closely related to radio astronomy (*g.v.*), since the supersensitive radar receiver can be used alone to listen to the many active emitters of radio waves, such as those from heat and gaseous sources within the solar system and from innumerable other sources both in our galaxy and beyond it.

The first radar contact with the moon, about 250,000 mi. away, was made by the U.S. army signal corps in Jan. 1946, using a modified SCR-271 radar. This initial success was followed in 1958 with radar reflections from Venus, some 28,000,000 mi. distant, and in 1959 by radar contact with the sun, nearly four times as far.

Both the Venus contacts (by the Lincoln laboratory of the Massachusetts Institute of Technology) and the echoes from the sun (accomplished by researchers at Stanford university) required computer techniques for study of the echo patterns. The echoes, returning minutes after the transmission because of the enormous

distances involved, were so weak that they could not be immediately distinguished from the radio noises, both those received from without and those generated within the receiver circuits. But by recording the received signals and processing them with an electronic computer, researchers were able to separate out the echo pattern. From it they could determine something of the nature and characteristics of the reflecting body. With improved equipment and techniques radar astronomers expected to be able to map the planets in considerable detail.

III. FACTORS AFFECTING RADAR PERFORMANCE

1. The Free-space Radar Equation.—A radar set must detect the weak signal returned from a distant reflecting object. The radar equation is important because it connects the various quantities that govern the strength of the signal so received. This relation will not serve to determine the maximum range at which the radar can detect a target unless the minimum power which gives a detectable radar signal, S_{min} , is known. The value of this latter important quantity will be found to depend on many factors, not all of which are accessible to measurement.

In discussing the radar equation, we first assume the very simple case of free-space propagation of the radio waves used in radar. This corresponds to a situation in which (1) no large obstacles intervene between the radar antenna and the target, along the optical line of sight; (2) no alternate transmission path, via a reflecting surface, exists for the radio energy; (3) the intervening atmosphere which must be traversed by the radio energy is homogeneous with respect to index of refraction at the frequency used; and (4) no appreciable absorption occurs in the atmosphere.

These conditions restrict our attention to radar targets within the optical horizon, and in fact to targets high enough above the horizon to avoid important effects (*see below*) which arise from the reflection of an appreciable amount of energy from the surface of the land or sea. If the conditions of free-space propagation apply, the transmitted radio wave has spherical wave fronts (limited in extent by the directional properties of the antenna) which spread out in such a way that the intensity of the radio wave changes with the inverse square of the distance from the radar antenna.

If the transmitting antenna radiated energy uniformly in all directions, the power flow through unit area at a distance R from the antenna would be the transmitted power, P , divided by $4\pi R^2$. Most radar antennas are directive, however, and concentrate the energy in certain directions, so that the power flow observed at some distant point will differ by a factor G from that which would be produced by an antenna radiating uniformly the same total power. The quantity G is called the gain of the antenna in the direction in question. Its average taken over a complete sphere surrounding the antenna must clearly be unity. As radar antennas are ordinarily highly directive, we shall usually be interested in the maximum value of G , which we call G_0 . When the radiating system, or antenna, can be regarded as an aperture of large area (measured in square wave lengths), over which a substantially plane wave is excited, we can write a useful expression for the maximum antenna gain, G_0 . The maximum antenna gain is related to the antenna area A and the wave length λ by the following relation:

$$G_0 = \frac{4\pi A d}{\lambda^2} \quad (2)$$

For actual antennas, the dimensionless factor d is usually about 0.6.

A second important property of an antenna is its effective receiving cross section. This quantity, whose dimensions are those of area, yields the total signal power available at the terminals of an antenna when an incident plane wave of unit power per unit area falls upon it. Effective receiving cross section is related to antenna gain as follows:

$$A_r = \frac{G\lambda^2}{4\pi} \quad (3)$$

In this equation, G has been written instead of G_0 to emphasize that the applicability of eq. (3) is not limited to the direction of maximum gain or to beams of special shape. Once the gain of an antenna in a particular direction has been specified, its effective receiving cross section for plane waves incident from that direction is fixed.

To obtain a measure of the amount of power reflected by the target, we define the radar cross section of the target, σ , as follows: σ is to be 4π times the ratio of the power per unit solid angle scattered back toward the transmitter, to the power per unit area in the wave falling on the target. In other words, if the power falling on an area σ located at the target position were to be scattered uniformly in all directions, the power received at the radar would be just the same as it is in the case of the actual target. Ordinarily, σ must be inferred by measurements on actual targets, since it depends in a complicated way on the wave length and on the angle at which a target is viewed.

We are now ready to formulate the radar equation. If S is the signal power received, P the transmitted power, G the antenna gain, λ the wave length, σ the radar cross section of the target, and R the range, or distance between radar and target,

$$S = \left(\frac{PG}{4\pi R^2} \right) \left(\frac{\sigma}{4\pi R^2} \right) \left(\frac{G\lambda^2}{4\pi} \right) \quad (4)$$

The quantity in the first parentheses gives the power density at the target; when we multiply by the second parentheses we obtain the power which returns to the radar antenna; the last factor is the receiving cross section of the antenna. Rearranging,

$$S = P \frac{G^2 \lambda^2 \sigma}{(4\pi)^3 R^4} \quad (5)$$

This equation contains G , not G_0 , and is thus valid for any direction. Usually we are interested in the return signal when the target lies somewhere along the direction the radar beam is pointing; G should then be replaced by G_0 . If we then write G_0 in terms of A , according to eq. (2), we obtain

$$S = \frac{P \sigma A^2 d^2}{4\pi R \lambda^3} \quad (6)$$

The received signal power is proportional to the power of the transmitted signals, to the radar cross section of the target and to the square of the antenna area. It is inversely proportional to the wave length squared, and to the fourth power of the range. If the minimum signal power required for detection, S_{min} , is known, we can rearrange eq. (6) to give the maximum range of detection, R_{max} , for a target of given cross section, σ :

$$R_{max} = \sqrt[4]{\frac{P \sigma A^2 d^2}{4\pi S_{min} \lambda^3}} \quad (7)$$

To help fix ideas, it will be useful to give a numerical example of the use of this equation, with values for the quantities involved which were not unusual in wartime pulse radar practice. Let $\lambda = 0.10$ ft. (≈ 3.0 cm.), $P = 10^5$ watts, $A = 10$ ft.², $d = 0.6$, $\sigma = 100$ ft.² (the radar cross section of a small aircraft) and $S_{min} = 5 \times 10^{-12}$ watts. We then obtain $R_{max} = 155,000$ ft. or 29 statute miles.

A sixteenfold increase in transmitted power is required to double the maximum range. It would appear that R_{max} could be doubled by doubling the linear dimensions of the antenna. However, this change cannot be discussed so simply, as the decrease in radar beam width resulting from making the antenna larger indirectly affects S_{min} . A change in wave length is also difficult to discuss, since it produces changes in S_{min} , P and possibly σ as well.

2. The Minimum Detectable Signal.—The reason that S_{min} has a finite value, and cannot be made indefinitely small, is that an amplifier intended to increase the power of a feeble electrical signal always produces random electrical fluctuations, called "noise." As the true signal entering any receiver is made weaker and weaker, it subsides eventually into the fluctuating background of noise and is no longer discernible.

The limit of sensitivity of an ordinary low-frequency radio

receiver is set, not by internal noise, but by similar random disturbances which originate outside the receiver. These disturbances enter the receiver by means of the antenna, so that the effectiveness of a desired signal in competition with such interference is the ratio of signal to the interference power at the antenna terminals. The absolute level of interference power throughout the conventional radio bands (down to a few metres wave length) is so high that internal noise in a reasonably well-designed radio receiver is negligible by comparison.

The situation is different in the microwave region, where external noise interference is almost wholly negligible. Great effort has, therefore, been put on reducing the inherent noise of microwave receivers.

Quite general theoretical considerations give the result that the mean square noise voltage unavoidably generated in a receiver is proportional to the width of the band of frequencies amplified by the receiver. This band width will be denoted by B . The excellence of a receiver in respect to its noise output is usually specified in terms of an over-all noise figure, N . This quantity is more or less arbitrarily defined as the ratio to the quantity kTB of the signal power at the antenna necessary to make the output signal power equal to the mean noise power. In this definition, k is Boltzmann's constant (1.38×10^{-28} joules/degree), and the temperature T is taken as 291°K .

Over-all noise figures of 10 were not uncommon for the best postwar microwave receivers. A noise figure of 10, at a bandwidth of 3 mc., means that an input signal of 1.2×10^{-18} watts is sufficient to increase the receiver output by an amount equal to the average noise output.

When a receiver is designed to detect pulses of duration τ seconds, there will be a best choice for the band width B . As already remarked, the average noise power increases in proportion to B . However, this does not mean that B should be made as small as possible, for when B becomes much less than $1/\tau$, the output signal power resulting from each pulse will be proportional to B^2 . Experiment has shown that the best value of B is about $B = 1.2/\tau$, but it can be changed by small amounts from this best value without serious effect on performance. In the mid-1950s, a value of B near $2/\tau$ was typical of pulse radar practice.

What has just been said does not yet constitute a specification for S_{\min} , the minimum detectable signal. The noise with which a signal must compete for recognition is statistical in character; that is, while the likelihood of large noise peaks is small, such large peaks do occur. For example, in the output of a receiver whose band width is 2 mc., there is better than an even chance that one noise peak having more than 20 times the power of the average will be seen in an hour's observation. About 100 noise peaks greater than 10 times the average will be observed each second. This random character of the magnitude of noise peaks makes signal detection largely a game of chance. It is a game of chance in which several factors favour an actual signal, however. A true radar echo is repeated at the same point on the indicator for each successive sweep, while noise peaks occur at random locations. This important difference between a signal and noise can either be used by the indicator directly—if the indicator screen shows a stronger signal for repeated excitation in the same place—or by the eye and mind of the observer. The latter means is astonishingly effective, as has been shown by experiment. The practical effect of this phenomenon of integration, whether it occurs in the indicator or in the mind of the observer, is to make S_{\min} depend upon the pulse repetition frequency, n , of a radar approximately in proportion to $1/\sqrt{n}$.

The problem of actual signal detectability is much more complicated than has been indicated here. It should be noted, however, that the very strong dependence of signal power on range shown by eq. (6) illustrates the fact that most signals which are at all detectable will be very strong.

3. Propagation of Short Radio Waves.—We shall now examine the principal ways in which propagation conditions near the surface of the earth and through the atmosphere introduce effects which are not included in the free-space radar equation, eq. (6). This is a vast subject, and only a few of the basic con-

siderations can be mentioned here.

Effect of a Reflecting Surface.—If the transmission path between radar and target lies near a reflecting surface, energy may be able to reach the target (and scattered energy to return to the radar) by way of reflection from the surface, as well as directly (fig. 3). In the case of a flat, perfectly reflecting surface, the ratio, W , between the actual power at the point B of fig. 3 and the power which would have been observed at B for free-

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 3.—WAVE PROPAGATION OVER A FLAT REFLECTING SURFACE. RADAR ANTENNA AT A, TARGET AT B

space conditions, can be readily computed. It depends on (among other things) the phase change produced in the reflected wave by the process of reflection. This phase change depends on the angle of incidence, θ , on the state of polarization of the incident wave and on the electrical properties of the reflecting surface. In radar, only grazing angles of incidence are practically important, and only the surface of the sea is sufficiently smooth to be an adequate reflector for microwaves. Under these circumstances, the ratio of the power actually reaching B to that which would reach it under free-space conditions is given by

$$W = 4 \sin^2 \left(\frac{2\pi h_1 h_2}{\lambda R} \right) \quad (8)$$

This ratio, as shown by eq. (8), varies between 0 and 4; the latter value being attained when the direct and reflected waves arrive at the target exactly in phase, as they will do when $4h_1 h_2 / \lambda R$ is equal to an odd integer. As the geometry of the problem is not affected by interchanging source and target, the reflection must affect the return of the radar echo to the same degree as it affects the pulse transmission. Therefore the required modification of the radar equation is obtained by multiplying the radar equation for free-space propagation by W^2 , giving

$$S = P \frac{G^2 \lambda^2 \sigma}{(4\pi)^2 R^4} \cdot 16 \sin^4 \left(\frac{2\pi h_1 h_2}{\lambda R} \right) \quad (9)$$

The effect of this modification is to introduce a strong dependence upon target height into the expression for the signal returned by a target to a radar which looks out over the surface of the sea. This is important for ship-based and coastal radar sets.

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 4.—LOBES OF SIGNAL-STRENGTH PATTERN RESULTING FROM INTERFERENCE OF DIRECT AND REFLECTED WAVES

Target height can be estimated by noting the ranges at which signal "fades" occur.

For targets at low angles (i.e., in the region where $\frac{2h_1 h_2}{\lambda R} \ll 1$) we can replace the sine in eq. (9) by its argument, obtaining

$$S = 4\pi P \frac{G^2 \sigma (h_1 h_2)^4}{\lambda^2 R^5} \quad (10)$$

In this region of angles, the signal strength falls off as the in-

verse eighth power of the range, rather than as the inverse fourth power, if all other factors are held constant. Since the range at which this eighth-power dependence begins varies as the reciprocal of the radar wave length for fixed heights of radar antenna and target, the shortest radar wave lengths have a very considerable practical advantage when the primary task of radar is to search the sea for low-lying targets, the radar antenna itself being mounted at no great height.

Experiments have borne out this conclusion, and microwaves were commonly used for ship-based sea-search radar sets during and after World War II.

The Round Earth.—Since beams of microwave radio energy travel substantially in straight lines, the distance at which a radar whose antenna is at height h_1 can see a target at height h_2 will be limited by the optical horizon. Actually, the diminishing density of the air with increasing height above the surface of the earth gives rise to a vertical gradient of atmospheric index of refraction, with the result that a slight downward curvature is introduced into all rays. The effect of this curvature is to extend slightly the practical horizon for microwaves. Due to a chance numerical relation between units, the following easily remembered formula gives R_h , the range to the horizon under "standard" conditions, for a height h above the surface of the earth:

$$R_h(\text{statute miles}) = \sqrt{2h(\text{feet})} \quad (11)$$

If we desire to find the greatest range at which a radar whose antenna is at height h_1 can see a target at height h_2 , we must add the corresponding horizon distances, obtaining

$$R = R_{h1} + R_{h2} = \sqrt{2h_1} + \sqrt{2h_2} \quad (12)$$

Radio waves in the ordinary communication bands (down to a few metres wave length) are propagated over the horizon by either of two effects. At the longest wave lengths, the energy is bent over the horizon by the phenomenon of diffraction; but energy can also travel around the curve of the earth, far beyond the horizon, because of the reflection of radio waves from the ionosphere, the ionized layer in the upper atmosphere. At radio frequencies around 100 mc. there is little reflection from the ionosphere; in the microwave region, from about 1,000 mc. up to higher frequencies, the ionosphere is transparent to radio waves. Thus neither diffraction effects nor ionospheric reflection can

FIG. 6.—ATTENUATION CAUSED BY WATER VAPOUR (CURVE A) AND BY OXYGEN (CURVE B) AS A FUNCTION OF WAVE LENGTH. CURVE A APPLIES TO AN ATMOSPHERE CONTAINING 10 G. OF WATER VAPOUR PER CUBIC METRE. CURVE B APPLIES TO AN ATMOSPHERE WHICH IS 20% OXYGEN AND HAS A TOTAL PRESSURE OF 76 CM. OF MERCURY

enable microwave radar to detect targets over the horizon, but there is some extension of range due to refraction in the lower atmosphere.

Within the horizon, the curvature of the earth complicates somewhat the geometry of the interference problem involving reflection. Eq. (9) and (10) are not strictly applicable, for they were derived on the assumption of a flat reflecting surface. The result of taking the earth's curvature into account can be shown by means of a coverage diagram (fig. 5). The curves of fig. 5 are contours of constant field strength, which means that the signal received from a given target will be the same no matter where it is located along a given contour.

Superrefraction.—It has already been mentioned that the atmosphere normally shows a vertical gradient of refractive index that results in a slight downward bending of rays of light or microwaves. Were this curvature only a few times greater, it would equal the curvature of the earth; under such conditions the "horizon" would vanish and a ray would bend around the earth without leaving the surface. Refractive index gradients of the magnitude necessary to produce such curvature amount to about five parts in 10^8 per ft. Under some conditions such gradients can be produced by temperature gradients alone, or, more commonly, by a vertical gradient in the concentration of water vapour in the atmosphere. Over the surface of the sea, the effects of evaporation of water into the air immediately above the surface and the diffusion of water vapour into still higher layers of air lead sometimes to the creation of a relatively shallow layer just above the water within which the vertical gradient of refractive index is negative and exceeds the critical value of five parts in 10^8 per ft. In such circumstances, superrefraction takes place, and it is possible for microwaves to be propagated to distances many times the usual horizon distance. This phenomenon is specially common in certain parts of the world where climatic conditions favour its occurrence.

Atmospheric Attenuation.—At the shortest microwave lengths, the earth's atmosphere is not entirely transparent, as it is for all practical purposes to waves of frequency lower than about 1,000 mc. The loss of energy, or attenuation, of a radar beam traveling through the atmosphere may be due to: (1) direct absorption of energy in the gases of the atmosphere; or (2) absorption and scattering of energy by condensed matter such as raindrops. All such processes lead to an exponential decrease of energy in the beam with increasing distance from the source.

This exponential decrease is superimposed on the inverse-square decrease in energy with increasing range that was used in formulating the radar equation. Of the atmospheric gases, oxygen and water vapour absorb microwave energy in the frequency range experimentally used for radar. This absorption is due to the production thereby of a transition of the molecule of water vapour or of oxygen between two definite energy states. The observed absorption is thus characterized by "lines," such as those found in more familiar regions of the electromagnetic spectrum. Experimental results (solid lines) and their theoretical extension (dotted lines) are shown in fig. 6.

Energy is also absorbed and scattered by particles of solid and liquid in the atmosphere. Droplets of water, present as fog, cloud or rain, are practically the most important particles of this sort. The attenuation by water droplets is of little practical consequence at wave lengths of 10 cm. or more, although sufficient energy is scattered from storm areas to give echoes at all microwave lengths. At wave lengths shorter than 10 cm., increasing attenuation is observed. Experimental results are given in fig. 7.

4. Target Properties.—Some useful things can be said about the radar cross section, σ , of various targets. In the case of the simplest single targets, σ can be calculated by electromagnetic theory; for other simple cases an approximate calculation will yield good results. Values of radar cross section of typical simple targets may be computed as follows:

(1) Dielectric sphere of radius small compared with wave length. Sphere radius a , dielectric constant ϵ , wave length λ .

$$\sigma = 4\pi \left(\frac{2\pi}{\lambda} \right)^4 \left| \frac{\epsilon - 1}{\epsilon + 2} \right|^2 a^6 \quad (13)$$

(2) Metal sphere of radius small compared with wave length.

$$\sigma = 9 \left(\frac{2\pi a}{\lambda} \right)^4 a^2 \quad (14)$$

(3) Flat metal sheet of area A placed perpendicular to radar beam. Dimensions of plate large compared with wave length.

$$\sigma = \frac{4\pi A^2}{\lambda^2} \quad (15)$$

(4) Cylinder of radius R and length l , both large compared with wave length. Cylinder is viewed perpendicular to axis.

$$\sigma = 2\pi \frac{R^2 l}{\lambda} \quad (16)$$

(5) Segment of spherical surface of radius R , viewed either on concave or convex side. Diameter of segment, perpendicular to the incident beam, must be greater than λ .

$$\sigma = \pi R^2 \quad (17)$$

Eq. (17) is also valid for a nonspherical curved surface, if the geometric mean of the two principal radii of curvature is used for R .

An important type of simple target is the corner reflector. This is used when a compact radar target with a large cross section in any direction of observation is desired. It consists of an arrangement of three planes intersecting at right angles. The law of optical reflection yields the result that a ray directed into the corner formed by three such planes will undergo triple reflection and be sent back in the direction from which it came (see fig. 8). The maximum radar scattering cross section of such a corner, which it exhibits when viewed along the axis of symmetry of a single corner, is

$$\sigma_{\max} = \frac{4\pi a^4}{3\lambda^2} \quad (18)$$

where a is the length of an edge of the corner and λ the radar wave length. The cross section remains large over most of the

FIG. 8.—PRINCIPLE OF THE CORNER REFLECTOR

octant for which a single corner is effective; all directions can be covered by making a cluster of eight such corners (fig. 9).

Radar cross section can be reduced by the use of materials absorbent at radar frequencies. Such materials are of two principal types. In the first kind, reflections occurring at the front surface of the absorber are cancelled by destructive interference with the wave that enters the layer and subsequently re-emerges.

Such absorbers are similar to the anti-reflection coatings applied to glass. Absorbers of the second kind are designed so that no

reflection takes place at the front surface and high attenuation in the material extinguishes the entering wave. A continuous gradation from one kind of absorber to the other exists.

During World War II, the Germans produced a material of the first kind which was used for the camouflage of U-boats, to lessen the likelihood of radar detection of a surfaced submarine. An absorber of the second kind, which was never actually used, was also produced by the Germans. Its absorption was excellent over the wave length range from 4 to 13 cm.

Complex Targets.—Most radar targets are much more complicated than the simple ones so far mentioned in this section. For such complex targets, the effect of interference of waves reflected from various parts of the target is extremely important in determining the strength of the received signal.

Ground "Painting" by Radar.—Air-borne radar equipment was extensively used in military aircraft during World War II for navigation by pilotage under conditions of restricted visibility.

Point-to-point variations in the radar reflection properties of the earth's surface enable the radar indicator to display a picture which, at best, shows a good relation with a map. Radar displays a marked contrast between land and water surfaces because of the greater diffuse scattering of the radio waves by the former.

Cities and groups of structures on the ground return a bigger signal than open country, possibly in part because of the retrodirectivity of the corner reflectors formed by building walls and the ground. Mountains and ridges can be distinguished by increased intensity on the near side and shadows cast beyond. The higher definition available with narrow-beam equipment using the shortest microwave lengths is important in giving a display which is easy to interpret. In all cases, however, experience and skill of the operator are important in making a good correlation between the radar picture and the ground beneath, especially inland in rather featureless country. Misidentification is so easy under these and other circumstances that air-borne radar must be regarded as an aid to dead reckoning, rather than a complete means of navigation in itself.

When the aircraft position is known to an accuracy of 20 or 30 mi., the radar display can hardly be interpreted incorrectly, even by an inexperienced operator.

IV. CW RADAR SYSTEMS

Since radar echo signals are so very feeble in comparison with the transmitted energy, they must be detected by some property which differentiates them from the transmitted signal in a readily measurable way. In pulse radar, this is done by turning off the transmitter for most of the time, so that signals received during the "off" time of the transmitter can be identified as echoes. It is possible to recognize echoes, however, even while the transmitter is working, on any of several schemes. Radio detection devices that involve a transmitter duty ratio of as much as 10% (in pulse radar this duty ratio is typically 0.1%) will be lumped here under the name CW radar. Devices of this sort have found important practical applications. (See NAVIGATION.)

If the targets of principal interest all have a radial motion relative to the radar, their echo signals can be distinguished by the frequency shift which is a consequence of the reflection of waves from a moving mirror. This frequency shift, f_d , is given by $(2v_r/c)f$, where v_r is the radial velocity, c the velocity of light and f the unmodified radar frequency. Numerically, with v_r in statute miles per hour and f defined by a wave length λ in cm. (equal to c/f), the frequency shift, which is called the "Doppler frequency," is given by

$$f_d = 89.4 \frac{v_r}{\lambda} \quad (19)$$

Thus at 10-cm. wave length, v_r amounts to about 9 c.p.s./m.p.h.

The Doppler-shifted return signal, when added to the transmitter voltage and rectified, gives rise to a voltage with small pulsations recurring at the Doppler frequency. The steady component can be removed by a high-pass filter (which may be simply a transformer or a series condenser) and the fluctuations then amplified and used to actuate an indicator. If the output signal is fed to ordinary telephone receivers, the ear can detect signals denoting the presence of a moving target over the range of World War II aircraft speeds, if the radar works at 10-cm. wave length.

CW radar systems of the type just described, with suitable technical modifications that do not affect the principle of operation, were built during World War II. Although they were not used in actual combat, they proved most useful in making precise measurements of the velocities of projectiles.

The system just described, though measuring the radial velocity of a target in a simple and accurate way, affords no information

regarding target range. To measure range, the outgoing wave must be marked or modulated in some way, and the time required for the marks on the wave train to return as an echo must be measured. Either amplitude modulation (AM), or frequency modulation (FM), of the outgoing wave can be used.

The most familiar way of employing AM is that of pulse radar to determine the time delay between the transmission and reception of a pulse. However, we can also measure range by the use of two separate CW radar systems like the one described above, the transmitter frequencies of the two differing by an amount f_r . Let f_o be the frequency of one transmitter and $f_o + f_r$ that of the other. The Doppler frequencies developed by the two systems when they look at a single target moving radially will differ, since these Doppler frequencies involve the transmitter frequency, as eq. (19) shows.

If the target is very close to the system, the number of wave lengths in the distance from transmitter to target and back is very nearly the same for the two systems, since their frequencies differ only slightly. Thus the transmitter signal and the target signal will be in phase or out of phase with one another at the two receivers simultaneously, and the two Doppler outputs will be in phase for very short range. As the target gets farther away, one Doppler signal shifts phase more rapidly than the other, so that a phase difference between the Doppler outputs of the two systems is developed. When the target is far enough away so that the number of wave lengths to the target and back is one greater for $f_o + f_r$ than it is for f_o , the phase difference in the outputs is 2π . This phase difference, which is given by

$$\phi = \frac{4\pi r f_r}{c} \quad (20)$$

where ϕ is the phase shift, r the range, and c the velocity of light, is a linear function of range and can be used as a measure of range. It becomes ambiguous for targets so far away that the phase shift is greater than 2π .

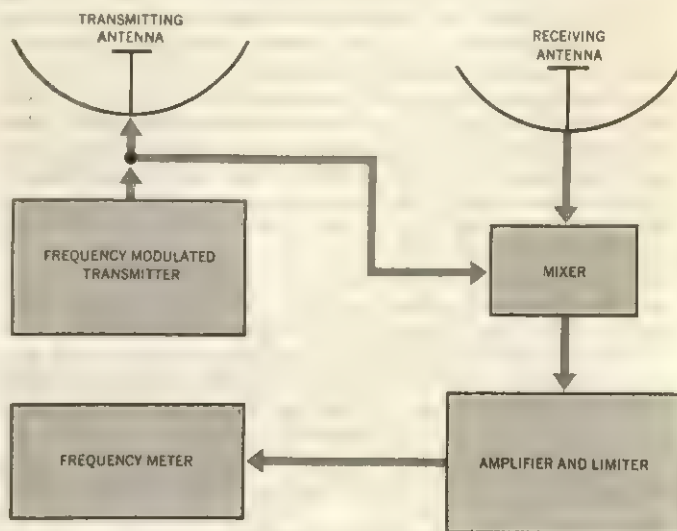

1. Range Measurement by FM.—One of the most important applications of CW radar systems during World War II was their use for the measurement of the altitude of aircraft with reference to the earth or sea below. A system employing frequency modulation of the transmitted signal was developed for this purpose in the U.S., and independently a very similar system was worked out in Germany.

A schematic diagram of the system components is shown in fig. 10; the operating principle of the system is illustrated by the curves of fig. 11. The transmitter frequency varies linearly with time in the fashion shown. Energy arrives at the receiver both directly from the transmitter and by reflection from the target. Since the trip to the target and back takes time, the received fre-

FIG. 10.—SIMPLIFIED BLOCK DIAGRAM OF FREQUENCY-MODULATED CW RADAR SYSTEM FOR MEASURING RANGE

quency (indicated by the dotted line) is displaced along the time axis relative to the transmitter frequency. The two frequencies combine in the mixer to give a beat of constant frequency (except during the short crossover intervals when the sign of the FM is changing). The greater the target distance, the greater this beat frequency; its magnitude is a direct measure of the range. The beat signal between transmitter signal and echo is therefore amplified, and its frequency measured by a direct-reading frequency meter which can be calibrated in terms of range.

If it is desired to use this same principle for radar search several targets may give return signals simultaneously. The receiver output will then contain several signals at different frequencies. These can be individually detected either by a frequency meter which will respond to and indicate several signals simultaneously, or by scanning a single-frequency meter over the frequency range corresponding to the target distances which must be covered. The vibrating-reed frequency meter will serve as an example of the first technique. In the second method, for example, a variable frequency can be added to the output signal and observations made when the beat frequency between the two signals falls in the pass band of a resonant circuit. Scanning devices are usually objectionable because they increase the time necessary to make an observation.

In addition to the CW radar systems whose operating principles have been sketched, there are many other types that involve different schemes of modulation of the transmitted signal and different techniques for handling the received echo. Though the amount of wartime development work which went into such CW systems was only a very tiny fraction of that expended on pulse radar, there are various applications for which CW radar is markedly superior.

For example, in accurate measurement of ranges as small as ten feet, a CW system is simpler than pulse radar. A system making use of the Doppler shift in frequency will measure the speed of a bullet in an easy and direct way and to any desired degree of accuracy. Or again, simple equipment may be desired, as in the familiar speed-detector radar employed in policing highway traffic, involving operation at short ranges (using microwaves of about 1 cm. in length).

V. RADAR COMPONENTS

1. The Multicavity Magnetron.—Beginning about 1938, the British made strenuous efforts to develop sources of high-power pulses at microwave frequencies, because of the importance of narrow radar beams in the air-borne equipment they were then attempting to develop. The modification of conventional tube types offered little promise; since to a first approximation, the electronic characteristics of a low-frequency tube are maintained at high frequency only if all tube dimensions are scaled in proportion to the wave length, λ . Near 1,000 mc., the practical consequences of this reduction in tube dimensions become serious. Electrode clearances become so small they are hard to maintain, while the reduction in cathode and plate areas (proportional to λ^2) rapidly reduces peak emission and plate power dissipation.

An entirely new type of tube, the multicavity magnetron, was invented to serve the new requirement. By the 1950s, magnetrons had produced pulse powers as high as 10,000,000 watts at frequencies near 3,000 mc., and hundreds of kilowatts even at 24,000 mc. Klystrons are useful sources of continuous RF power at frequencies as high as 24,000 mc. and can also be designed to give high pulse power.

The magnetron is a self-excited oscillator capable of converting D.C. power into RF power with high efficiency. The main features of the design of a typical magnetron are shown in fig. 12.

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 11.—PRINCIPLE OF FM RADAR ALTIMETER

Between the indirectly heated cylindrical cathode and the anode block is an interaction space in which the conversion takes place. A constant, uniform, magnetic field is maintained in this interaction space in a direction parallel to the axis of the cathode. The anode block is pierced in a direction parallel to the field by a number of resonating cavities, which open into the interaction space so that the inner anode surface consists of alternate segments and gaps. At the ends of the cavities are open "end spaces" which permit lines of magnetic flux to link one resonator to the next. Coupling between the resonators is increased by conducting bars called straps, which connect together alternate anode segments. An output coupling loop extracts RF power from one resonator and feeds it to the output circuit.

Each of the eight resonant cavities shown in fig. 12 can be thought of as a simple oscillating circuit consisting of lumped inductance L_0 and capacity C_0 . When the magnetron is oscillating in the desired way, the capacities of the individual cavities are connected in parallel, and so are their individual inductances. The frequency of the magnetron as a whole is then about the same as that of an individual cavity, since the frequency is proportional in either case to the product of inductance and capacity. The impedance of the oscillators, however, depends on L_0/C_0 , and magnetrons of the same frequency but different impedance can be constructed by changing the shape of the individual resonators to keep L_0C_0 constant while altering L_0/C_0 .

Like all systems of coupled individual oscillators, the resonant systems of a magnetron can oscillate in different modes; in general these modes will have different frequencies. One of these modes has been found to be by far the most desirable from the standpoint of reliable operation, and much attention has been paid to the problem of making the frequency of the desired mode sufficiently different from that of any other to encourage the magnetron to oscillate in the desired mode. The straps shown in fig. 12 are primarily for this purpose of accomplishing mode separation in frequency; another way of achieving such separa-

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 12.—CROSS SECTIONS OF A TYPICAL CAVITY MAGNETRON. MAGNETIC FIELD PERPENDICULAR TO UPPER FIGURE; VERTICAL IN LOWER FIGURE

tion is to make the alternate individual resonators of different natural frequencies.

Instead of a tube such as that of fig. 12, intended to be put between the poles of an electro-magnet or a permanent magnet, a tube can be built in which the magnet pole tips are actually part of the construction of the magnetron proper. In this way, the air gap over which the magnetic field must be maintained is cut down, and as a result the required magnetomotive force (and the physical size of the magnet) can be greatly reduced. Permanent magnets are usually employed with magnetrons.

An electron in the interaction space is acted on by a constant magnetic field parallel to the cathode axis, a constant radial electric field resulting from the D.C. voltage applied between anode and cathode, and the rapidly varying electric field extending into the interaction space from charges momentarily concentrated near the ends of anode segments. Such an electron is also part of a space charge subject to extreme variations in density. The very complex problem of the resulting electron motion has not been solved in detail, but a qualitative idea of the major processes responsible for magnetron behaviour can be given.

A simplified picture of the motion of individual electrons is offered in fig. 13. The distribution of charges shown on the anode segments is that appropriate to the desired mode of magnetron operation. The dotted lines with arrows show the resultant electric field. An electron located at point A at the instant shown will be speeded up by the RF field. The result of an increase in the tangential velocity of an electron is, under the field conditions obtaining in the magnetron, to increase the curvature of the electron's path. The electron thus moves along the path shown, strikes the cathode, and plays no further role in the operation of the magnetron.

An electron at point B, however, is in a decelerating RF field; the curvature of its path will thus be decreased. If the frequency of oscillation is appropriate to the motion of the electron, this electron will always be in a decelerating field as it passes before successive anode segments. It will then follow a path of the sort shown, and eventually strike the anode. Since the electron is always retarded by the RF field, it gives up to the RF field practically all of the energy gained in its fall through the D.C. field between cathode and anode. While this simple picture is qualitatively correct, the detailed operation of a magnetron is doubtless much more complicated. One experimental fact difficult to explain, for example, is that the anode efficiency of some magnetrons can be as high as 85%.

The behaviour of the space charge in the interaction space can be inferred from what has been said about the motion of an individual electron. The result is shown in fig. 14. Four spokes of high electron density are in the proper position to be decelerated by the RF field. This configuration rotates about the cathode with an angular

FIG. 14.—SPACE-CHARGE DISTRIBUTION IN AN OSCILLATING MAGNETRON. INSTANT SHOWN IS THAT OF ZERO RF ELECTRIC FIELD. LINES OF RF MAGNETIC FIELD ARE INDICATED WITHIN CAVITY RESONATORS

velocity which keeps it in step with the alternating RF charges on the anode segments. The RF current flowing in the oscillators is principally a displacement current produced by this rotating space charge. Fig. 14 shows the space charge at an instant when the RF electric field is zero; the lines of magnetic field in the resonators are shown.

The behaviour of a magnetron with changes of anode current and of pulse voltage can be displayed on a performance chart, which shows how these parameters affect frequency, power, magnetic field and efficiency under conditions of constant RF load.

The magnetron as it has so far been described is a fixed-frequency device. However, several different schemes have been worked out for tuning cavity magnetrons. In one way or another, each of these schemes involves loading the resonators so as to change their natural frequency of oscillation.

2. Pulse Modulators.—The modulator, or pulser, of a radar set is a somewhat unusual electrical device. It must supply, in the form of electrical pulses whose duration is in the range from $1/10$ to 5μ sec., currents of some tens of amperes at voltages as high as 50 or 60 kv. These pulses must be generated with a recurrence frequency of a few hundred to a few thousand per second, usually must be accurately spaced relative to one another and, since the magnetron is such a highly nonlinear load, they must be "flat" on top to better than 5% of the rated pulse voltage. In a typical case, a variation in pulse voltage of only 3 kv., will produce, in a magnetron operating at 25 kv. and 13.5

amp., a drop in anode current of 7 amp., which practically stops the oscillation of the magnetron.

In all pulsers, electrical energy is released rapidly during the pulse, and replenished during the interval between pulses. Energy can be stored either in the electrostatic field of a condenser or in the magnetic field of an inductance carrying a current. Pulsers employing electrostatic energy storage are far more common than those using an inductance as the storage element, largely because power losses in the latter type of pulser are ordinarily much greater for the same useful pulse output.

The following discussion refers

FIG. 15.—BASIC CIRCUIT OF A PULSER EMPLOYING ELECTROSTATIC ENERGY STORAGE.

The basic circuit of a pulser is shown in fig. 15. If the energy-storage element is a condenser of capacity C , charged to a voltage V , the stored energy is $\frac{1}{2}CV^2$. At $t = 0$ the switch S is closed, and the condenser begins to discharge exponentially through the load resistance. If S is now opened suddenly at a time τ small compared with the time constant $R_L C$ of the circuit, the voltage appearing across the load while the current is flowing is given by

$$V_L(t) = V(1 - \frac{t}{R_L C}), \quad 0 \leq t \leq \tau \quad (21)$$

which is constant within a few per cent if $\tau < R_L C$.

In practice, vacuum tubes are the only switches that can be used to open the load circuit suddenly while it is still carrying a large current. The plate resistance of such tubes is always rather large, resulting in a high voltage drop across the switch during the pulse, and a corresponding loss in pulser efficiency. It would be desirable to use a very low-resistance switch, such as a spark or gaseous discharge, to eliminate this difficulty. However, all such devices have the property that the current flow through them, once started, cannot be interrupted until the voltage across the switch has fallen to an extremely low value. Thus,

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

if such a low-resistance switch were used with a pulser having a simple condenser for an energy-storage element, the condenser would have to be completely discharged at each pulse. This is unsatisfactory, since the wave shape of the output pulse would then be exponential instead of being substantially rectangular, as desired.

If, however, a transmission line is used as an energy-storage element instead of a condenser, its discharge properties under the appropriate load conditions are such that it will supply energy at constant current until it is completely discharged. This is exactly what is wanted for the generation of rectangular pulses. Elementary transmission-line theory shows that if a line of inductance L and capacity C per unit length is charged to a voltage V and then suddenly connected across a resistance R_L , a discontinuous current of magnitude $V/(Z_0 + R_L)$ will flow for a time $2t$, where Z_0 is the characteristic impedance of the line ($= \sqrt{L/C}$) and t is its one-way transmission time. If $R_L = Z_0$, no current flows after a time $2t$, and a genuinely rectangular pulse has been generated. The time t is given by l/\sqrt{LC} , where l is the physical length of the line.

Since the pulse durations desired in radar are usually a micro-

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 16.—SCHEMATIC DIAGRAM OF A PULSE-FORMING NETWORK. NUMBER OF MESHES REQUIRED DEPENDS ON DURATION OF PULSE

TABLE I.—Comparison of the Two Pulser Types

Characteristics	Hard-tube pulser	Network pulser
Efficiency	Lower; more power required for auxiliary circuits and for dissipation in switch tube	High, particularly when pulse-power output is high
Pulse shape	Better rectangular pulses	Poorer rectangular pulse, particularly through pulse transformer
Impedance matching to load	Wide range of mismatch permissible	Smaller range of mismatch permissible (± 20 – 30%). Pulse transformer will match any load, but power input to non-linear load cannot be varied over a wide range
Interpulse interval	May be very short; as for coding beacons (i.e., 1μ sec.)	Must be several times the de-ionization time of discharge tube (i.e., 100μ sec.)
Voltage supply	High-voltage supply usually necessary	Low-voltage supply, particularly with inductance as isolating element
Change of pulse duration	Easy; switching in low voltage circuit	Requires high-voltage switching to new network
Circuit complexity	Greater, leading to greater difficulty in servicing	Less, permitting smaller size and weight

second or more, it is ordinarily impracticable to use actual transmission lines or cables in pulsers; a cable to supply a $1\text{-}\mu$ sec. pulse would be about 500 ft. long. Instead, an "artificial line" (fig. 16) made up of properly chosen inductances and condensers is used. Such an artificial line is sometimes called a "pulse-forming network." A pulser employing a network as storage element is less flexible than one which uses a condenser and hard-tube switch, since the properties of the network itself fix the pulse duration and the load impedance. Components available for network construction make it desirable to give the network a low impedance; 50 ohms is typical. The magnetron load usually has a much higher impedance, in the neighbourhood of 500 ohms. Specially designed "pulse transformers" are used to match the load impedance to that of the network.

Devices used as the low-impedance gas-discharge switch in a network pulser include rotary spark gaps, fixed spark gaps in series, fixed gaps with an auxiliary electrode for triggering (called "trigatrons"), and thyatrons using either mercury or hydrogen as the filling gas. Hydrogen thyatrons were developed specifically for radar pulsers, and have the advantage over heavy-gas thyatrons in that they can pulse at much higher frequencies, because of the higher ion mobility in hydrogen.

The charging circuit used with either type of pulser so far

considered—the "hard-tube" pulser which uses a single condenser as storage element, or the "network" pulser which uses a low-voltage switch—is an important part of the circuit. In the hard-tube pulser, the energy source must clearly supply direct current for recharging. The isolating element prevents excessive power from being drawn out of the energy source when the switch is closed (fig. 15), and must also permit sufficient energy to flow in the interpulse interval to replace that used during the pulse. In the hard-tube pulser, it can be either a high resistance, an inductance or a series combination of resistance and inductance.

In the case of the network pulser, on the other hand, the full energy of the charged network must be supplied by the recharging circuit after each pulse. This means that a resistance is a very inefficient isolating element, for as much energy will be dissipated in it, each time the network is recharged, as is usefully stored in the network. Accordingly, an inductance is almost always used as an isolating element. Further, the network can be recharged from an alternating-current source, provided the pulse repetition frequency is a multiple of one-half the A.C. supply frequency. An extremely simple high-power pulser can be made by mounting a rotary spark gap switch directly on the shaft of the A.C. machine supplying the recharging current for the network. The hard-tube and the network types of pulser have different fields of usefulness. A comparison of their properties is shown in Table I.

3. Radio-frequency Components.—A considerable body of new theory and technique grew up during the development of microwave radar because of the necessity of handling power at frequencies so high that the wave length of the RF energy is of the same order as the physical size of the circuit elements. The length of a microwave transmission line may be, and usually is, several wave lengths. For a fuller description of RF techniques at microwave frequencies, reference should be made to the works quoted in the bibliography.

Coaxial Line.—A transmission line is characterized, as already remarked, by a characteristic impedance which depends upon the inductance and capacity per unit length of line, and is thus a function of the geometry of the insulators and conductors of which the line is made. In a coaxial line, a type frequently used for the transmission of high-frequency energy (fig. 17), the characteristic impedance, Z_0 , is given by

$$Z_0 = \frac{138}{k} \log_{10}(r_2/r_1) \text{ ohms} \quad (22)$$

where k is the dielectric constant of the material in the annular space between the conductors, r_2 is the inner radius of the outer conductor, and r_1 is the outer radius of the inner conductor.

A uniform line terminated at any point in a load duplicating its characteristic impedance behaves as if it were infinitely long; there is no reflection of energy from the termination. However, any impedance changes along the line (such as those introduced by dents, bends or obstacles in the line), or any departure of the load from the characteristic impedance of the line, will cause the reflection of energy. The reflected wave, which travels back toward the power source, interferes with the outgoing wave to produce standing waves in the line. These can be detected and measured by exploring the voltage along the line with a small movable probe, such as that shown in fig. 17. There will

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 17.—SLOTTED SECTION OF COAXIAL LINE WITH PROBE FOR MEASURING STANDING WAVES

be voltage maxima spaced at half-wave length intervals with minima halfway between them. A line which is properly terminated and uniform, so that it exhibits no standing waves, is said to be "matched."

When a lossless transmission line a quarter-wave length long and of characteristic impedance Z_0 is terminated in an impedance Z_L , the input impedance of the line is

$$Z_i = Z_0^2 / Z_L \quad (23)$$

This property enables two transmission lines of different impedance to be matched to each other by joining them through a quarter-wave line whose characteristic impedance is the geometric mean of the impedances of the two lines. Such a quarter-wave section is called a "matching transformer." If a quarter-wave line is terminated by a short circuit, its input impedance is infinite; conversely, an open-circuited quarter-wave line appears at the input terminal to be a short circuit.

For a lossless line a half-wave length long,

$$Z_i = Z_L \quad (24)$$

irrespective of the characteristic impedance of the line.

At microwave frequencies, the losses in the solid dielectrics used to insulate the inner from the outer conductor in a coaxial line are prohibitive at the power levels usually encountered. "Stub-supported" lines have therefore been developed (fig. 18), in

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 18.—BROAD-BAND STUB SUPPORT FOR CENTRE CONDUCTOR OF COAXIAL LINE

shown in fig. 18, this frequency sensitivity is compensated, over a band of $\pm 15\%$ of the base frequency, by the quarter-wave transformers formed by the fat sections of the centre conductor near the stub support.

Rotary joints which permit mechanical motion while transmitting RF power without reflection or mismatch are often required.

Standard coaxial line usually has a characteristic impedance of 50 ohms, this corresponding to a ratio of 2.3 for the radii of the outer and inner conductors. This is a compromise between a ratio of 3.6 (77 ohms) which, for a given outer diameter, gives the lowest attenuation due to conductor losses, and a ratio of 1.65 (30 ohms) which enables the maximum power to be carried at a given breakdown voltage gradient across the dielectric.

The size of a coaxial line is limited by the wave length of the

radiation transmitted. The electric fields within a coaxial line have axial symmetry if the line is small enough. If, however, the mean circumference of the annular dielectric space between the conductors exceeds one wave length, a second "mode" of propagation of the RF energy can be excited. In this second mode, the field distribution has diametral symmetry. Since serious design complications arise if it is possible for two modes of propagation to be excited simultaneously in an RF line, the overall size of coaxial line is always kept so small that only the axially symmetric mode of propagation can exist. The resulting limita-

tion on power-handling capacity has restricted the use of coaxial lines to wave lengths of 8 cm. and more.

Wave Guide.—At shorter wave lengths, and for handling the highest powers even in the 10-cm. band, a wave guide is used.

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 19.—TRANSITION FROM STUB-SUPPORTED TWO-WIRE TRANSMISSION LINE TO WAVE GUIDE

Though a metallic pipe of almost any shape will transmit or guide electromagnetic waves whose wave length is short enough, rectangular tubing whose internal dimensions have a ratio between 2.0 and 2.5 is ordinarily used to transfer microwave energy. Though a detailed understanding of the propagation of RF energy in wave guide demands the solution of Maxwell's equations with the appropriate boundary conditions, we can get a picture of the mechanism of this propagation by considering the resemblance between a rectangular wave guide and a two-wire transmission line.

Fig. 19(A) shows a two-wire line with a single short-circuited stub support, analogous to the coaxial quarter-wave stub support already described. At the proper frequency, the input impedance of the stub is very high and the stub has no effect on the propagation of the wave on the line. In fig. 19(B) a great many stubs, extending both ways from the two-wire line, have been added, still without affecting the propagation of the frequency in question. In fig. 19(C) the stubs have been coalesced into a rectangular tube which looks like a wave guide. For a single stub, a slight correction to the length must be made to compensate for the

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 20.—FUNDAMENTAL MODE OF WAVE PROPAGATION IN A RECTANGULAR GUIDE. SOLID LINES ARE THOSE OF ELECTRIC FIELD; DASHED LINES SHOW CURRENT FLOW IN WALLS; DOTTED LINES SHOW MAGNETIC FIELD

inductance of the crosspiece, but when the stubs become a solid tube, no lines of force can link the narrow side, and the quarter-wave distance becomes exact. This also shows why the length of the narrow side of the rectangular tube is not critical.

All frequencies higher (wave lengths shorter) than that for which the quarter-wave stubs of our model were designed can be transmitted by wave guide. In such a case (fig. 19 [D]) the two wires become broad bus bars with only as much of the wide side given over to stubs as is required by the now shorter wave length. Wave lengths greater than twice the broad dimension of the guide cannot be propagated because then the stubs become less than a quarter-wave long and shunt the line with a rather low inductive impedance which would extinguish the wave.

Fig. 20 shows an instantaneous picture of the electric and magnetic fields in a rectangular wave guide whose wide dimension is slightly more than half the free-space wave length of the radiation being transmitted. Lines of current-flow in the walls are also shown. As the dimensions of the wave guide increase relative to the wave length of the radiation being transmitted, modes of propagation different from that illustrated (*i.e.*, having different space distributions of electric and magnetic field) can be excited.

As in the case of coaxial line, this is almost always objectionable, and the maximum size of the broad dimension of a rectangular wave guide is usually chosen to be less than 0.95 of the free-space wave length of the radiation to be transmitted.

Each type of wave guide has a cutoff frequency for propagation in the lowest mode. Waves of higher frequency are transmitted; those of lower frequency are rapidly attenuated. The wave length of the radiation inside the guide is longer than the free-space wave length and is given by

$$\text{Guide wave length} = \lambda_g = \frac{\lambda}{\sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}} \quad (25)$$

where λ is the free-space wave length and λ_c is the cutoff wave length. For the lowest mode in rectangular guide, as we have seen, the wave length corresponding to the cutoff frequency is twice the broad dimension. This sets a lower limit to the practical size of wave guide. Its broad dimension is usually chosen to be greater than 0.6 times the free-space wave length, because of

FIG. 21.—TRANSITION FROM COAXIAL LINE TO WAVE GUIDE

design complications that ensue if the cutoff value of 0.5λ is approached too closely.

The narrow dimension of rectangular guide is chosen as large as possible to raise the breakdown field strength (the electric field being across this narrow dimension); but it must be less than half a free-space wave length of the radiation to be transmitted, so that there is no possibility of transmitting a wave polarized at right angles to that shown in fig. 20.

Transitions between wave guide and coaxial lines usually take the form of a quarter-wave stub antenna on the coaxial line projecting into the wave guide at the proper distance from a reflecting end plate, as shown in fig. 21. Rotary joints make use of quarter-wave choke sections. The power-handling capacity of wave guide is more than double that which can be realized by the largest coaxial line it is practical to use; the attenuation in a given length of wave guide is about half that encountered in coaxial line. Mechanically, wave guide is superior, being easier to fabricate and more difficult to damage in use.

Resonant Cavities.—If both ends of a wave guide are closed by short-circuiting plates, and energy is introduced by a probe or through a hole so small that the properties of the enclosure are not affected, the resulting box is called a resonant cavity. When its length is an integral number of half-wave lengths of the radiation in the guide, the reflections from the end plates will reinforce one another and cause a resonant build-up of the energy in the cavity. Because the wave length in the guide differs from that in free space, as shown by eq. (25), the shortest resonant piece of a wave guide whose broad dimension is $1/\sqrt{2}$ free-space wave lengths is also $1/\sqrt{2}$ free-space wave lengths long. The narrow dimension of the cavity does not affect the resonant wave length, though it should be less than $\lambda/2$ to avoid the possibility of exciting the cavity in a mode polarized at right angles to the one desired.

The sharpness of resonance exhibited by a resonant cavity at microwave frequencies is very great. It is usually measured by a number called the Q of the cavity. If f_0 is the resonant frequency and f_1 and f_2 are the two frequencies, one above resonance and one below, at which the voltage in the cavity is 0.707 that at resonance, then

$$Q = \frac{f_0}{f_1 - f_2} \quad (26)$$

The Q of a 10-cm. cavity made of copper is typically as great as 15,000. This is much higher than the Q of resonant circuits made of coil-and-condenser combinations, for use at lower frequencies, because of the great effectiveness of a resonant cavity as a device for the storage of energy.

TR and ATR Switches.—Resonant cavities are used in the construction of the TR and ATR switches needed to permit duplex operation of a radar transmitter and receiver on a single antenna. Fig. 22 shows schematically how gas-discharge switches, fired by the high-power RF pulse from the magnetron, can be mounted to perform the TR and ATR switching functions. Breakdown of the TR tube puts a low-resistance short circuit across the receiver line, thus protecting it; but since this short circuit is a quarter-wave length away from the junction with the antenna line, there is no attenuation of the wave traveling toward the antenna. Break-

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 23.—CUT-AWAY VIEW OF 1B24 3-CM. TR SWITCH

down of the ATR closes the circuit from magnetron to antenna; when the pulse is over and the ATR discharge goes out, the im-

pedance at the T junction looking toward the magnetron is infinite because there is an open circuit half a wave length away. Looking toward the receiver, there is a matched line, so that all the echo power goes into the receiver.

To reduce the voltage necessary to break down the discharge gaps of the TR and ATR switches, they are filled with gas at a pressure of about 1/200 atmosphere. Further reduction is accomplished by mounting the discharge gap across a resonant cavity, to make use of the build-up in voltage accompanying resonance. Fig. 23 is a cutaway view of a TR tube used in the 3-cm. band. The resonant cavity is part of the tube envelope, and is made to be bolted between standard wave guide coupling flanges. Energy is coupled into and out of the cavity by means of round holes (filled with glass to retain the gas) in each side of the cavity. The discharge takes place between the two conical electrodes in the centre of the cavity; tuning is accomplished by moving one of them, mounted on a flexible diaphragm, toward or away from the other. To ensure rapid breakdown of the gap at the beginning of a pulse (within $0.01 \mu \text{ sec.}$), a supply of ions is maintained in the gap by a discharge taking place constantly inside one of the cones.

ATR tubes are similar, except that they need have no output window, being mounted on the side of (i.e., in series with) the RF line. Ordinarily they are made with lower Q , to reduce the chance of accidental maladjustment of tuning.

In the years following World War II, use of the newly developed ferrite materials, which exhibit a very pronounced Faraday effect at microwave frequencies, permitted the construction of circuit elements which were highly nonlinear, in the sense that they behaved differently for microwave energy traveling in opposite directions. This made possible the design of duplexing and isolating elements less complicated and more effective than the gas-discharge devices of wartime radar.

4. Antennas and Scanners.—The antenna of a radar set must radiate into space the energy fed to it as RF pulses, and must gather in the echo signals and send them down the RF line to the receiver. A good transmitting antenna is also a good receiving antenna; thus only the former function need be considered. Sharp beams are needed to make radar direction-finding possible, and a great deal of attention has been paid to the design of highly directional antennas that are capable of producing beams of the desired shape and dimensions. The nature of the beam wanted depends, of course, on the radar application.

Antenna Design.—The beam width, θ , produced by an antenna is directly proportional to the wave length of the radiation used, and inversely proportional to the width of the antenna. Beam width as usually defined is the full angular interval between the points at which the power radiated from the antenna has fallen to half its maximum value (fig. 24). Fig. 24 shows also the "side lobes," small subsidiary maxima unavoidably produced by a directional antenna. Their effects are usually objectionable, and attention is paid in antenna design to reducing the power in

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 24.—A TYPICAL ANTENNA PATTERN. MAIN LOBE HAS BEAM WIDTH θ . SIDE LOBES ARE SHOWN

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 25.—RAY DIAGRAM OF A PARABOLOID ANTENNA

the side lobes. The beam width in degrees is given approximately by

$$\theta = 70\lambda/D \quad (27)$$

where λ is the wave length and D the width of the antenna in the same dimension as that for which θ is measured. D and λ should be given in the same units.

Among the simplest microwave antennas is a reflecting paraboloid of revolution illuminated by a source of radiation, or "antenna feed," placed at its focus. Since the diameter of the reflector is several wave lengths, this antenna can be regarded from the standpoint of ray optics (fig. 25). Fig. 25 does not explain the side lobes or the beam width, but it does emphasize that the feed for such an antenna must itself be directive.

In accordance with eq. (27), a paraboloid whose top and bottom have been cut off to leave a reflector wider than it is high will produce a fan-shaped beam whose vertical beam width is larger than its beam width measured horizontally. A "beaver-tail" beam wider in the horizontal than in the vertical direction can be produced by cutting off the sides of a paraboloid to leave a tall, narrow reflector. Further adjustment of the energy in the beam can be accomplished by altering the shape of the reflector without changing its over-all dimensions.

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 26.—HELICAL SCANNING PATTERN

Instead of a paraboloidal reflector with a feed at its point focus, a parabolic cylinder with a linear feed located along its line focus can be used as an antenna.

Mechanical Scanning.—In order to cover the necessary volume of space with the narrow beam produced by a directional antenna, the beam must be swung around, or scanned. In most cases, the permissible rates of beam motion, fixed as they are by the desirability of receiving several echo pulses from each target per scan, are so low that scanning can be accomplished by mechanical motion of the antenna array. The assembly of an antenna on its supporting structure, or pedestal, is called an antenna mount, or scanner.

Radar scanners are of many different sorts, the detailed design being dictated principally by the size of the antenna (this being determined by the wave length used and the beam width desired), and by the scanning pattern used to cover the volume being searched. A few simple scanning patterns are:

(1) *Azimuth scan.*—The beam is swung around the horizon at a uniform rate. The desired vertical coverage is obtained by fanning the beam in the vertical direction.

(2) *Helical scan.*—If information on the elevation angle of targets is wanted, a pencil beam can be used, uniform azimuth rotation employed and the elevation angle of the beam altered constantly at a slow uniform rate (fig. 26). When the full elevation-angle range of interest has been covered, the motion in elevation angle is reversed.

(3) *Conical scan.*—For accurate direction-finding on a single target, a pencil beam can be rotated rapidly in a cone whose angular opening is smaller than the beam width. Only when the axis of the cone is directly pointed at the target will the signals received in various phases of the rotation of the beam have constant intensity. A change

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 27.—SPIRAL SCAN

in signal strength will accompany conical scan when the axis of the cone is not quite on the target. The magnitude and phase of this change in signal strength as the beam rotates indicates the direction and the magnitude of the pointing error. The direction of the cone axis is changed to make the "error signal" zero. By the use of this scheme, radar direction-finding can be given a precision of about one-fiftieth of a beam width; this is far greater precision than can be obtained by noting the direction of maximum signal return when a beam is swept over a target.

(4) *Spiral scan*.—If a rapid axial rotation of a pencil beam, like that used in conical scanning, is combined with a slow change in the cone opening, a spiral scan (fig. 27) results. This permits rapid coverage of a fairly large area, with facilities for determining roughly both the azimuth and the elevation of targets.

Data Transmission.—In order to make use at the radar indicator of the directional information afforded by scanning, means must be provided for transmitting to the indicator a knowledge of the scanner position in all important co-ordinates. Only azimuth must be transmitted for an azimuth scan, azimuth and elevation for a helical scan, and azimuth, elevation and phase of rotation for a conical or a spiral scan.

This "data transmission," as it is called, is almost always accomplished electrically. The flexibility of mechanical means of data transmission is not sufficient to meet radar requirements. Self-synchronous generators and motors of the type used in other applications for transmitting position information are frequently employed. So are precision adjustable resistors. The latter have the advantage that they can be wound in such a way that the output voltage is any desired function of angle of rotation. Further, the applied voltage, to which the output voltage is proportional, can be varied in any fashion desired. Thus computation can be performed directly by the data transmission device.

For example, suppose it is desired to find target height, h , from a measurement of range, R , and elevation angle, ϕ ; it will be given by

$$h = R \sin \phi \quad (28)$$

If the resistance card of the adjustable resistor used to measure elevation angle is so wound that its output voltage for an elevation angle ϕ is proportional to $\sin \phi$, and the voltage applied to this resistor is developed from another adjustable resistor used to measure range and having an output linear with R , then the voltage at the output terminals of the elevation-angle resistor will be a direct measure of the height of the target. A highly successful anti-aircraft computer was built during World War II on this principle. When used with radar, the data-transmission units of the radar actually formed part of the computing mechanism.

Rapid Scanning.—In some radar applications, such rapid scanning is desired that mechanical motion of a large antenna mount is not feasible. A number of devices have been developed to permit rapid scanning in one dimension by relatively subtle mechanical motions of parts of the antenna. These devices are sometimes referred to as "electrical" scanners, although rapid mechanical motion is almost always fundamental to the scanning.

Stabilization.—When a radar scanner is mounted on an unstable platform, such as a ship or an aircraft, readings of azimuth and elevation relative to the platform must be converted into readings of these angles with respect to a stable set of reference axes. Compasses, directional gyros, and gyro stable verticals are commonly used as reference devices, and the stabilization of the radar data, as this conversion process is called, can be performed in a variety of ways.

5. Radar Receivers.—Under the term "receiver" is classed that part of the radar equipment which accepts the feeble echo pulses from the RF line, amplifies them, rectifies them and delivers to the terminals of the indicator or display equipment unipolar

pulse signals at a level usually of several volts.

Most radar receivers are of the superheterodyne type, in which a local oscillator supplies CW signals at a low level to a mixer, where

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 29.—LIGHTHOUSE TUBE MOUNTED IN A COAXIAL CIRCUIT

the echo signal and the local oscillator signal beat to give a signal at a frequency (called the intermediate frequency) equal to the difference between the frequencies of the signals mixed. This beat signal is modulated with the same intelligence as that conveyed by the RF echoes, and its frequency is chosen to permit fairly standard techniques to be used in the IF amplifier.

The IF amplifier is normally tuned to a fixed frequency, and the receiver tuning is changed by altering the frequency of the local oscillator. Arrangements, called AFC (for automatic frequency control), are incorporated in most radar receivers for keeping the local oscillator properly tuned with respect to the radar transmitter. Demodulation of the amplified IF signal is accomplished by a second detector followed by a filter for the intermediate-frequency signal. The resulting signals, called "video signals" because their frequency range is about that of television video signals, are further amplified and sent to the indicator.

RF Amplifiers.—Development of the idea that an electron stream can interact and exchange energy with a traveling electromagnetic wave led to the development soon after the close of World War II of a type of vacuum tube called a traveling-wave tube. Some embodiments of this principle were useful for the hitherto impossible problem of amplifying energy at microwave frequencies.

By the early 1960s there were suitable RF amplifier tubes for all microwave frequencies in common use. They had not yet altered the need for mixer crystals as first detectors in superheterodyne receivers used in radar, but they gave substantial promise of improving radar performance.

Microwave Mixers.—Conversion to intermediate frequency in the mixer at the low level of received signal power requires that the nonlinear element used in the mixer be as efficient as possible and introduce a minimum amount of random noise. The most satisfactory element was the rectifying contact between a metallic point and a silicon crystal. The whole assembly was sealed up in a cartridge, referred to as a "crystal," for protection and stability. One standard form for this cartridge is shown in fig. 28.

The contact area between the metal and the silicon is only about 10^{-6} cm². High current densities are therefore produced even by low currents, and a crystal can readily be burned out, especially by a pulse so rapid that heat cannot be conducted away from the contact.

The RF circuit in which the crystal is installed is called the "mixer." It has input terminals for the signal and for the power from the local oscillator. Its output terminals are connected to the first stage of the IF amplifier. Care is taken in mixer design to make the crystal appear as a matched load to the incoming signal; to prevent, as far as possible, loss of echo-signal power into the local-oscillator input line; and to provide a reasonably good match looking into the mixer from the local oscillator.

Local Oscillators.—The magnetron, although a very efficient source of high pulse powers, was not employed in wartime radar as a source of the low-level CW signal required from the local oscillator of a superheterodyne receiver. Quite satisfactory tubes

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 28.—STANDARD MICROWAVE MIXER CRYSTAL

of other types were developed for this purpose.

Some World War II radar sets used a special triode, called a "lighthouse" tube because of its construction, as a local oscillator. The lighthouse tube is designed with planar electrodes and extremely small interelectrode spacing to reduce electron transit time. External connections to its electrodes are provided in the form of disks and cylinders (fig. 29), so that a cylindrical RF circuit can be built directly around the tube. An average power output of a few watts can be obtained from a lighthouse tube, and the tube can also be pulsed to give peak power of about 1 kw. It has been used as a transmitter in some low-power radar sets.

Most radar sets used a reflex klystron as a local oscillator. Fig. 30 is a schematic diagram of such a tube. Integral with the tube structure is a doughnut-shaped resonant cavity with grids across its central portion. An "electron gun" focuses a stream of electrons through the grids. Upon arrival at the first grid, the electrons have a velocity corresponding to the 300 volts applied to accelerate them. If oscillations exist in the cavity, electrons will either be accelerated or decelerated by the RF field which they encounter as they pass through the space between the cavity grids. An electron which goes through just as the RF field is passing through zero will not have its velocity changed, and will be described as a reference electron. In the space just beyond the second grid there is a strong retarding field produced by a reflector electrode maintained about 100 volts negative with respect to the cathode. The path of the reference electron in this retarding field is similar to that of a ball thrown into the air. It will return to the grids after a time proportional to the retarding field. An electron that leaves the second grid earlier than the reference electron will have been accelerated by the RF voltage which then existed across the cavity, and, because of its higher velocity, it will spend a longer time in the reflection space than will the reference electron. By proper adjustment of the retarding field, the delay can be made to compensate for its earlier departure, so that it arrives back at the grids at the same time as the reference electron. Similarly, an electron leaving later than the reference electron has been decelerated by the RF field, has a lower velocity, and thus catches up with the reference electron because it spends less time in the reflection space. The net effect is that the electrons gather in a bunch which is formed about the reference electron. At certain reflector voltages, the bunch will return through the cavity grids in such a phase that the RF field retards the electrons, and thus receives from them energy to sustain the oscillations in the cavity. Oscillation is observed for more than one reflector voltage, since drift times differing by a whole RF period still produce satisfactory bunching.

The net energy given to the electrons during their first passage

through the cavity is negligible when averaged over a whole RF cycle, being balanced between acceleration and deceleration.

FIG. 30.—SCHEMATIC DIAGRAM OF REFLEX KLYSTRON OSCILLATOR

On the return passage, most of the electrons go through in a bunch at the most favourable phase to aid the oscillation. Very few electrons pass through on the return trip half a cycle later, when they would absorb energy from the RF field. Power is coupled out of the cavity through a loop feeding into a coaxial line. Power outputs in the range from 20 to 50 mw. and efficiencies of about 1% were typical of such tubes produced in the postwar years.

Tuning over a wide range is accomplished by changing the size of the cavity mechanically; a small amount of tuning can be done by varying the reflector voltage.

Automatic Frequency Control.—The problem of keeping a radar set properly in tune consists in maintaining the difference between the local-oscillator frequency and the magnetron frequency constant at the value appropriate to the IF amplifier, with an accuracy of perhaps 0.5 mc. AFC is a practical necessity in scanning radar, for the magnetron frequency can be altered several mc. by changes in standing-wave ratio occurring in the RF system either in consequence of unsymmetrical rotary joints or because of strong reflections from nearby objects such as the masts of a ship or the engine nacelles of an aircraft carrying the radar. Further, variations in voltage, temperature and pressure all produce changes in frequency. Manual tuning is quite unsatisfactory, and AFC has come to be a standard part of all radar.

In the AFC system, part of the local-oscillator power is mixed, in a crystal, with a small fraction of the magnetron power drawn out during transmission of the pulse. The resulting signal at the difference frequency is applied to a discriminator circuit similar to those used in a frequency-modulation receiver. The crossover or no-output frequency of the discriminator is set at the intermediate frequency of the radar. The pulses which come from the discriminator are integrated to produce a voltage that is applied to the reflector of the local oscillator in the proper sense to change the frequency toward that value which will bring the discriminator output to zero. It is desirable to use an AFC mixer which is separate from the signal mixer, but it is possible to make an AFC system which obtains its information from the leakage power which inevitably reaches the signal mixer during the transmission of an RF pulse from the magnetron.

The IF Amplifier.—Because of the low power level of the input signal to a radar IF amplifier, the greatest attention must be paid to minimizing the inherent noise of the amplifier itself. Further, since strong pulses several hundreds of μ sec. in length may be followed immediately by weak signals which must not be missed, the transient response of the IF amplifier must be excellent. The amplifiers which resulted during World War II from attention to these requirements were rather different from anything which had previously existed.

The intermediate frequency is usually chosen in the range from 15 to 60 mc. The over-all gain of the IF amplifier is usually around 120 db. or 1,000,000 times in voltage. The desired over-all band width of the amplifier is ordinarily about 2 mc. Since the cascading of amplifier stages results in an over-all band width

AIR-BORNE RADAR DISPLAY SHOWING ECHOES FROM THE LAND AROUND THE IRISH SEA. THE ISLE OF MAN IS AT LOWER CENTRE (5 O'CLOCK)

much less than the band width of an individual stage, it is very important to attain the highest possible product of gain and band width in the individual stages.

The design of the interstage coupling circuit used in an IF amplifier has an important effect on the gain-band-width product

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 31.—RANGE SCOPES: (A) PIP MARKER; (B) STEP MARKER; (C) NOTCH MARKER

that can be achieved with given tubes. The characteristics of the tubes themselves are also of the greatest importance, the leading property being the ratio of transconductance to input and output capacity.

It is important that regenerative feedback of signals does not take place from later stages to earlier stages of the IF amplifier, or from plate to grid circuit in a single stage. Circuit layout and shielding must be carefully planned to avoid regeneration.

Second Detector.—The second detector produces a rectified voltage proportional to the amplitude of the IF waves. In most radio receivers it is important that this proportionality be exact; in a radar receiver the response of the second detector may be proportional to a higher power of the IF amplitude, so long as reasonable efficiency is maintained. Either a thermionic diode or a rectifying metal semiconductor contact ("crystal") is used as the nonlinear rectifying element. Second-detector crystals usually employ germanium, instead of silicon, as the semiconductor, since germanium crystals can be made to stand a somewhat higher reverse voltage.

Video Amplifier.—The unipolar signals from the second detector, usually at a level of a few volts, are further amplified by a wide band resistance-capacitance-coupled amplifier called the video amplifier, because of its similarity to the video amplifiers used in television.

When the line from the radar proper to the indicator must be long, it is economical to drive the line at a low video-signal level and provide video amplification at each indicator. Since the standard dielectric-filled coaxial cable ordinarily used for the transmission of video signals has a low impedance—in the neighbourhood of 75 to 100 ohms—a "cathode follower" stage is frequently used to drive the line.

6. Radar Indicators.—The device which presents radar data in observable form is called the indicator. It is almost always a cathode-ray tube (CRT). The CRT presents a representation of electrical phenomena in terms of a picture painted on a phosphorescent screen by a sharply-focused beam of electrons controlled in position and intensity by electrical signals. The CRT

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 32.—J-SCOPE, ANOTHER TYPE OF RANGE SCOPE SHOWING READING IN (A) THOUSANDS OF YARDS; (B) HUNDREDS OF YARDS

is capable of using and displaying many millions of separate data per second, and the geometrical expression which it gives to radar data is particularly appropriate, since a geometrical situation involving the various radar targets is usually precisely what must be represented.

CRT Screens.—Both magnetic and electrostatic CRT types are used, the terms referring to the means of deflecting the stream of electrons (fig. 1). The properties of the materials (phosphors) making up the luminous screen are of particular importance to the performance of the tube. If, as is usually the case, the scanning of the radar antenna interrupts the display in a given sector of the screen for longer than the retentivity time of the eye, it is desirable to introduce persistence into the screen—that is, to use a phosphor which will glow for some time after having been excited.

If little or no persistence is needed, the green willemite phosphor used in ordinary oscilloscope tubes and known as type P-1 is satisfactory. This material is extremely efficient in converting the energy of the electrons which strike it into luminous energy; it has an exponential decay with a time constant of a few milli-

FIG. 33.—DISPLAYS PERMITTING COMPARISON OF STRENGTH OF ECHO FROM A GIVEN TARGET ON TWO ANTENNAS, OR IN TWO POSITIONS OF A CONICAL SCAN. (A) SIDE-BY-SIDE PRESENTATION (K-SCOPE). (B) BACK-TO-BACK PRESENTATION (L-SCOPE)

seconds. If a rather short persistence is needed, a zinc-magnesium fluoride phosphor designated as P-12 is used.

Most radar applications demand even a longer persistence. This can be achieved by a "cascade" screen consisting of two layers of different phosphors. The electrons strike and excite an inner layer of silver-activated zinc sulphide, which glows with a blue light. This blue light excites a layer of persistent phosphor, usually copper-activated zinc-cadmium sulphide. The zinc-to-cadmium ratio determines the decay characteristics.

Because the long-persistence phosphor emits a predominantly yellow or orange light, an orange filter is used to remove the blue "flash" of the inner phosphor, which is annoying to the observer.

Radar Displays.—Because of the many special purposes that radar can serve, a considerable variety of different forms of display have been developed and used. The A-scope and the PPI have already been mentioned. These are typical of two general classes in which the radar echo signals are used either (1) to deflect the CRT electron beam, or (2) to alter its intensity. Displays of the first type (deflection-modulated displays) are useful for giving precise information on the strength and character of the signals delivered by the receiver, but leave only one dimension of the tube face free to represent a geometrical quantity. Displays of the second type (intensity-modulated displays) permit the presentation of a two-dimensional figure on which the signals appear as bright spots or patches, but the intensity response of CRT electron guns is so nonlinear that the brightness of each patch offers only qualitative information about signal intensity.

When a three-dimensional picture must be presented on the two-dimensional face of a CRT indicator, either more than one display must be used, or a formalized way of presenting the third dimension in an understandable, though unnatural, fashion must be devised.

The vast majority of radar displays use as one co-ordinate the

value of slant range to the target. Range is displayed by causing the electron beam of the CRT to sweep across the tube at a uniform rate starting from a given point or line at a definite time in each pulse cycle. Distances on the tube face from the starting point are then proportional to increments of range.

The angle at which the scanner is pointing, either in azimuth or elevation, may enter the display (1) directly as a polar angle, (2) directly as a Cartesian co-ordinate, or (3) as the basis for resolving a range sweep in a particular direction.

Usually markers are employed to assist in making measurements of range or angle on a radar indicator. These may be "electronic" markers introduced into the signal channel as artificial video signals generated by a precision timing circuit (for range markers) or an angle-measuring circuit (for angle markers). Alternatively, they may be mechanical grids or markers placed over the face of the CRT.

A few of the most important radar displays are catalogued below, according to the spatial geometry represented.

One-dimensional Deflection-modulated Displays.—The simplest display of this type is the A-scope described earlier. Range is invariably the spatial co-ordinate presented on a display in this class. If it is desired to do accurate range-finding with the help of an indicator in this category, arrangements are made to delay the start of the range sweep by any desired amount, so that the interval displayed will include the target of interest. The sweep speed is then greatly increased to give higher resolution in range. Usually a movable electronic marker is provided for the precise measurement of range. Such a display is called an R- (range) scope. Fig. 31 shows R-scope displays with various types of movable range markers.

Greater sweep length can be obtained by bending the range sweep into a circle on the face of the tube, and using the radar echo signals to deflect the beam radially from the centre of the CRT. Fig. 32 shows such a display called a J-scope.

Simple deflection-modulated range displays can be used for comparing the signal strength from two antennas whose patterns make a small angle with one another, or from a conically scanning antenna in two positions 180° apart. The K-scope is so arranged that the range sweeps to be compared start from different origins, so that the echoes to be compared are side by side. In the L-scope, signals from the two antennas produce deflections of opposite sign, the range origin being common (fig. 33).

Two-dimensional Intensity-modulated Displays.—The PPI is the most generally useful of the indicators in this category. For certain purposes, it is altered by moving the range origin (off-centre PPI), or by expanding the zero-range origin of the PPI into a circle (open-centre PPI), or by delaying the start of the sweep, so that a ring-shaped area is collapsed into a solid circle (delayed PPI).

A PPI can also be deformed by "stretching"; that is, by giving different scale factors to the two Cartesian co-ordinates of the display. Straight lines remain straight but, except for those parallel to the Cartesian axes, their directions are changed. If elevation, instead of azimuth, is the angular co-ordinate used on the scope, the resulting display is called a range-height indicator, or RHI. Lines of constant target height are horizontal and equally spaced. (See fig. 34.)

A plane surface can also be represented in a deformed manner useful for certain radar applications by presenting range and angle in Cartesian rather than in polar co-ordinates. This is accomplished by moving a range

sweep laterally across the tube face in synchronism with the scanner motion so that the range origin is stretched out into a line.

If the angular field shown by such a display is small enough, it can be "normalized" to reduce the distortion to modest limits. Normalization is performed by keeping the angular dispersion proportional to the range to the centre of the display.

Three-dimensional Displays.—

As already remarked, no real three-dimensional display can be presented on the two-dimensional face of a CRT. However, certain formalized ways have been developed for indicating target elevation on a display which already shows target range and bearing. An example of this type is the "double-dot" display. On alternate range sweeps the origin of this modified Type-B indicator is moved to the right and left sides by a fixed amount. On the sweeps occurring in the right-hand pattern the origin is simultaneously shifted vertically by an

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 35.—THE DOUBLE-DOT INDICATOR, A B-SCOPE IN WHICH EACH TARGET ECHO APPEARS TWICE. ANGLE OF LINE JOINING TWO SIGNALS SHOWS ELEVATION ANGLE OF TARGET RELATIVE TO AXIS OF RADAR SCANNER. TARGET A IS LEVEL WITH SCANNER, 1.5 MI. AWAY, AND DEAD AHEAD. TARGET B IS 4.5 MI. AWAY, 25° LEFT AND SLIGHTLY BELOW. TARGET C IS 2.5 MI. AWAY, 12° RIGHT AND ABOVE

amount proportional to the sine of the elevation angle.

Any single echo then appears in two neighbouring positions, and the slope of the line joining the two dots is a rough measure of elevation angle, accurate to two or three degrees under the usual circumstances of use. (See fig. 35.)

A Simple Indicator.—The electrical means of achieving the rapid and accurate sweeps for radar indicators are beyond the scope of this article, and the reader is referred to the works quoted in the bibliography. However, it will be useful to outline the functions of the important parts of a simple display system.

The parts of the indicator circuit concerned with the pulse repetition cycle are called the "timer." The timer provides a synchronization with the modulator, sweeps and markers for the display and measurement of range, blanking of the CRT during unused parts of the pulse cycle, and other related operations.

In some cases, the timer exerts control of the firing time of the modulator by sending it a trigger pulse; in others it responds to a trigger from the modulator. The latter type of system is shown in fig. 36. The square wave is used to turn the CRT on during the useful display cycle. The linearly increasing (or sawtooth) waveform is used to provide the uniform range sweep for the indicator.

Timing of this wave is controlled by the square wave. Electronic range markers are also generated by the timer and mixed with the radar video signals before they are sent to the CRT.

For illustrative purposes, fig. 36 shows provisions for either an A-scope or a B-scope display. For the former presentation, the range-sweep voltage is applied to one pair of deflecting plates and the mixed signal and range-mark voltages to the other pair. The square wave controlling the CRT intensity is applied to the cathode in the proper polarity to brighten the tube during the range sweep.

In the Type-B display, the range sweep is applied to one pair of deflection plates, as before. Signal modulation is applied to the control grid, and the second set of deflection plates receives a voltage which produces the azimuthal deflection. This voltage may be furnished, for example, by a linear potentiometer geared to the axis of rotation of the scanner.

The arrangement shown is equally applicable to a magnetic CRT, the only changes being in the deflection amplifiers.

VI. ACCESSORY DEVICES

1. Radar Beacons.—In nearly all cases where it would be advantageous if a particular radar echo could be made much stronger

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 34.—THE RANGE-HEIGHT INDICATOR (RHI). THIS IS A POLAR DISPLAY WITH DIFFERENT SCALE FACTORS ALONG THE TWO CARTESIAN CO-ORDINATES. THE VERTICAL STRETCHING IS SHOWN BY THE TWO-MILE GRID SHOWN DOTTED IN THE DIAGRAM. LINES OF CONSTANT HEIGHT ARE STRAIGHT AND HORIZONTAL ON THIS DISPLAY

or more readily distinguishable from other confusing echoes, a radar beacon is indicated. By the use of a beacon, particular aircraft can be identified among heavy ground echo signals, or in the midst of a large formation of aircraft; the exact location of a specific point on the ground can be indicated, and so on.

A beacon is a repeater of radar pulses. It has an antenna and receiver that convert pulses of energy received at high frequency from a radar set or a special beacon interrogator into triggering signals. Each such triggering signal fires the transmitter in the beacon and causes it to radiate one or more pulses of radio energy that may have almost any desired characteristics in regard to power, frequency, number, duration and spacing. A short time is required for the beacon to reply to an incoming pulse, so that the first reply pulse is slightly delayed beyond the radar echo which would be received from an object at the beacon location. This delay can be made as small as a few tenths of a microsecond (a few tens of yards in range); if this small delay is still not negligible, it can be made extremely constant and allowed for in interpreting the beacon signals.

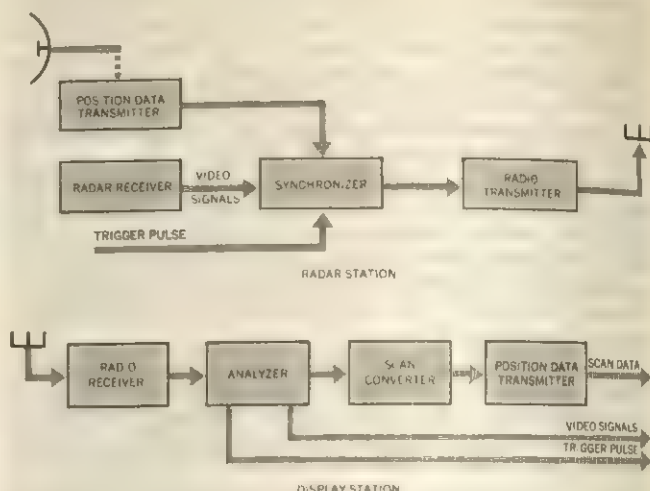

To permit the display of beacon signals alone, without radar echoes, the beacon transmitter frequency is ordinarily chosen to be different from the radar frequency. Beacon signals can be received at a radar set either by retuning the receiver to the beacon reply frequency, or by providing an extra independent receiver tuned to the beacon. Since the power of the beacon transmitter can be made as great as desired, there is no limit to the strength of the beacon reply. The range at which a beacon can be seen will then be limited only by the power of the radar transmitter and the sensitivity of the beacon receiver, which together determine whether the beacon will be triggered or not.

Since the beacon interrogation and reply links are independent, instead of being two paths for the same energy (as in the case of radar echoes), the range at which beacons can be challenged and their replies received is usually very great, and ordinarily limited only by the optical horizon. The interrogation signal at the beacon falls off as the inverse square of the range to the challenging radar; the reply of the beacon has a power at the radar which is the same function of range.

Beacons of the synchronous sort just described are variously called radar beacons, responder beacons, racons or transponders, there being no important distinction among these terms. Free-running beacons that are not triggered by a pulse challenge are seldom used in conjunction with radar sets, since from them only the bearing of the beacon can be determined, and not its range. Range is so useful a part of the data supplied by radar that beacons which enable its measurement are far preferable to those that do not.

In order to avoid overloading a beacon located where there are many radar sets, it is usually desirable to provide an interrogation coding arrangement whose purpose is to limit the beacon responses to only those interrogation pulses specifically intended to elicit such a response. The decoder is intended to serve this purpose. In the case of ground beacons serving as navigation check points for air-borne radar, it is customary to use pulse-width

discrimination in the decoder. The usual radar pulses of an air-borne set are one microsecond or less in duration; the beacon

FIG. 37.—ELEMENTS OF A SIMPLE RADAR RELAY SYSTEM FOR THE DIRECT TRANSMISSION OF RADAR INDICATIONS TO A REMOTE POINT BY RADIO MEANS

decoder is arranged to produce a trigger for the beacon transmitter only if it receives a pulse whose duration is two microseconds or more.

The air-borne radar is then fitted with a control which lengthens the transmitter pulses and simultaneously retunes the receiver to the beacon reply frequency when it is desired to look at beacon signals instead of at radar echoes.

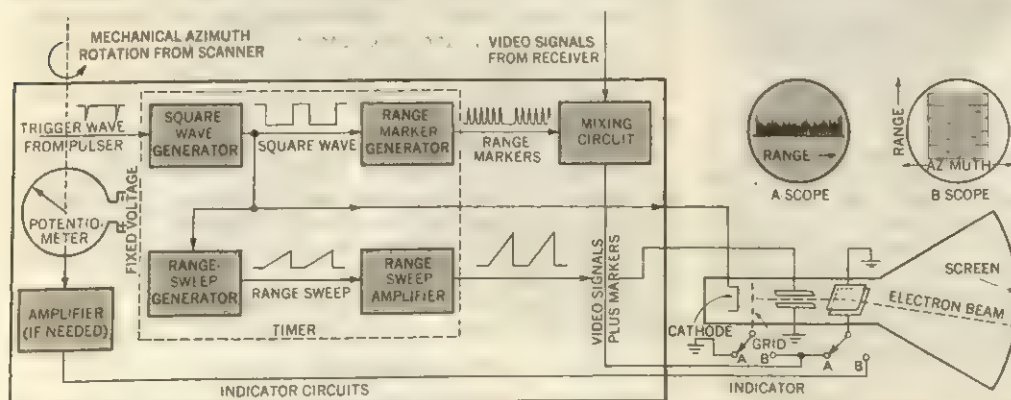

Reply coding is intended to identify the particular beacon whose response is seen. In the case of microwave radar beacons, this reply coding is usually "range coding," involving the transmission of a closely-spaced series of short pulses from the beacon transmitter.

Other possibilities for coding both interrogation and reply are numerous. Distinct frequencies can be chosen. Simultaneous challenge on two or more frequencies may be necessary to unlock the beacon and elicit a reply. Combinations of properly timed multiple pulses can be used. The beacon reply may be keyed on-and-off to send letters in Morse code. The particular coding system chosen will depend on the application.

Sometimes it is desirable to use, as the device intended to trigger a beacon and to display its replies, instead of a radar set, a much lower-powered device intended only to work with beacons. Such an equipment is called an interrogator-responder. It is a radar set in all respects except that its transmitter power is so low that radar echoes cannot be obtained at useful ranges. This reduction in power output enables the equipment to be made much lighter and simpler than a radar set at the same frequency.

The interrogator-responder can be especially small and light if

only range information is wanted from the beacons, so that a scanner is not necessary and fixed antennas can be used. By providing two sets of fixed antennas aimed in slightly different directions, homing on a beacon can be done by turning the aircraft or ship carrying the interrogator-responder until equal beacon responses are received on the two antennas. By altering the interrogation and reply coding of a beacon to correspond with intelligence which it is desired to transmit, two-way communication using a radar-beacon link is feasible and has been accomplished.

2. Radio Relay of Radar Displays.—It frequently happens that the best site for a radar equipment is not the best location for the organization which is to make use of the information provided by the radar.

For example, in the World War II organization for fighter defense of the British Isles against hostile air attack, the operating centre was maintained at Stanmore, north of London; information was sent there from radar sets located all around the coasts.

During World War II it was customary to transmit radar information from one point to another by "plotting and telling." The radar echoes seen were entered at the proper range and bearing on a map with a superimposed rectangular grid; this was plotting.

The letters and numbers comprising the grid reference for the location of the plot were "told" vocally over telephone lines or radio circuits to the control centre, where the targets were replotted.

This particular type of system has several drawbacks. Not only are there many chances for the introduction of errors in the target position, but also the speed and traffic-handling capacity of the system are severely limited. It has already been remarked that a radar indicator presents several million units of data per second. By no means are all of these significant, but in a situation involving hundreds of targets, which may not be at all uncommon, it is clearly impossible for even many tellers to give as useful a picture of the air situation as is available at the radar set.

For these reasons, methods were worked out during the war for transmitting, by a radio link, radar video information, synchronizing signals and signals giving the direction in which the radar scanner was pointing at any instant. At the receiving station, these data could be used to construct a radar indication whose quality was just as good as that of the indicators located at the radar set itself.

The problems are mainly those of any wide-band radio link, complicated by the fact that both pulses and long blocks of video signals must be transmitted and received. The elements of a system for accomplishing radar relay are shown schematically in fig. 37. Radar data are delivered to a "synchronizer" which arranges them in proper form to modulate the transmitter. At the receiving station, the receiver amplifies and demodulates the incoming signals and delivers its output to an "analyzer." The latter sorts out separately video signals, trigger pulse and scanner data. The video signals and the trigger are delivered immediately to the display system.

The scanner data must usually be modified in a "scan converter" before being used in display synthesis, because a code is ordinarily used for the transmission of scanner angle.

The scan converter uses the coded data to construct a duplicate of the scanner motion that can be used to drive a position-data transmitter connected to the indicators. The over-all requirements of the system are quite similar to those of television, since the band of frequencies which must be transmitted is about the same.

Comparative PPI photographs may be taken simultaneously at a transmitter and receiver several miles apart.

The direct relay of radar video signals is preferable to televising an indicator at the radar station and transmitting the information by television means, for the following reasons: (1) Persistent indicators do not televise well; their light is too far toward the red end of the spectrum. This leads to a loss in signal-to-noise ratio and in definition; (2) the display available at the receiving end must be identical with that scanned by the television camera at the transmitting end. If video signals are transmitted directly, any desired type of indication can be synthesized at the receiver.

The first, but not the second, of these objections can be removed by storing the radar information on an orthicon or other television pick-up tube directly, instead of viewing a CRT with a television pick-up.

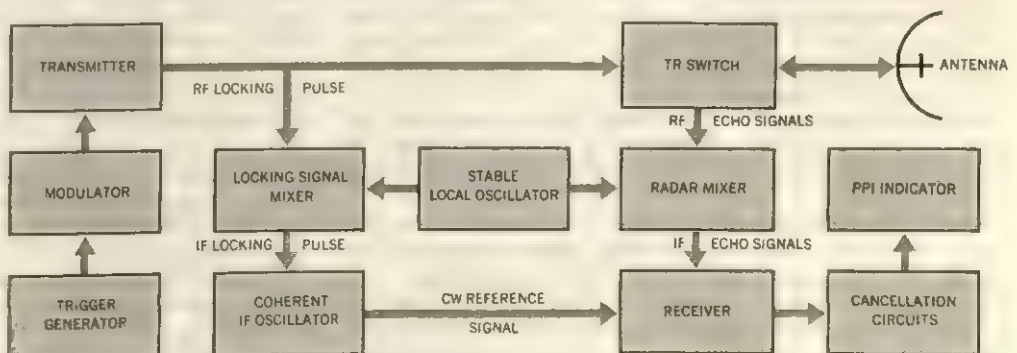

3. Moving Target Indication.—"Ground clutter," the system of strong permanent radar echoes returned by hills and buildings in the vicinity of a radar set, is often a limiting factor on the performance of radar, especially in mountainous terrain. Similarly, the echo signals returned by waves to a radar set carried on a ship or located on the shore ("sea clutter") can be most troublesome. CW radar often makes use of the Doppler shift in frequency of the signal returned from a target in radial motion relative to the radar, and thus responds only to moving targets. This same property can be conferred on pulse radar by special techniques, which will be described below, called MTI (moving target indication).

In pulse radar, the effect of the Doppler shift is to cause a phase shift from pulse to pulse of the echo from a moving target. If the radial velocity of the target is v , and the repetition period, or time between successive pulses, is T , each pulse travels a distance $2vT$ different from that traveled by the preceding pulse. This difference is $2vT/\lambda$ wave lengths, so that the phase change between each pulse and the one which follows it is $2\pi \times 2vT/\lambda$ radians. The Doppler frequency is $2v/\lambda$, in agreement with eq. (19).

The basic idea of MTI is to compare the phase of each echo on successive pulses. If there is no phase change, the target is stationary, and its signal is not passed to the indicator. If the phase changes from pulse to pulse, the target is moving, and its signal is displayed. The phase comparison is made in terms of a very stable oscillator which is adjusted, at the instant each pulse is transmitted, to have a standard phase with respect to the outgoing pulse. Beating the echo signal with that of this "coherent oscillator" will give a signal whose amplitude depends on the relative phase of the echo and the output of the coherent oscillator. If the echo comes from a stationary target, the amplitude of the signal which results from beating the echo with the coherent oscillator output will not change from one pulse to another. If the echo comes from a moving target, the amplitude of the beat will change from pulse to pulse.

It is not important in principle whether the coherent oscillator used as a phase reference runs at radio frequency or at the intermediate frequency of the superheterodyne receiver, provided that the local oscillator of the superheterodyne is stable. Since it is easier practically to have the coherent oscillator run at intermediate frequency, this scheme has been used. A schematic diagram of a practical MTI system is shown in fig. 38.

A stable local oscillator supplies a signal to two mixers, one of which provides a "locking signal" for adjusting the phase of the coherent oscillator to its standard value with reference to the outgoing RF pulse. The other mixer is the signal mixer of the receiver. When the IF echo signals and the IF reference signal beat against one another, the phase of the receiver output signal depends on the number of cycles executed by the local oscillator and by the coherent oscillator during the out-and-back time of travel of the pulse. The result is shown in fig. 39(A). Four suc-

FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 38.—SCHEMATIC DIAGRAM OF MOVING TARGET INDICATION (MTI)

cessive sweeps of an A-scope are shown, corresponding to four successive pulses.

It will be seen that four of the five echo signals seen on each trace are of constant amplitude from pulse to pulse, and thus correspond to stationary targets. The other echo signal shows a changing amplitude from pulse to pulse; this corresponds to a changing echo-signal phase, and indicates radial target motion.

The way in which stationary targets can be cancelled is shown in fig. 39(B). If the signals from successive pulse cycles are subtracted from one another, echoes of constant amplitude vanish, while echoes of changing amplitude do not.

The actual subtraction is performed by sending the receiver output to a "subtraction circuit" both directly and through a delay line which introduces an amount of delay exactly equal to the interpulse interval. Thus the subtraction circuit receives and compares echo signals from the immediately preceding pulse (direct from the receiver) and from the next earlier pulse (through the delay line).

The length of the usual interpulse interval is so long—some hundreds of microseconds—that electrical delay networks are impracticable for use in MTI. Instead, an ultrasonic delay device is often employed. Signals from the receiver output are turned into sound waves in a liquid or solid by a piezoelectric transducer, allowed to travel through the liquid or solid medium as ultrasonic waves for the distance necessary to introduce the required delay, and turned back into electrical signals by a transducer at the end of the medium.

The velocity of sound waves in such a medium as mercury permits the necessary delays to be produced by sonic paths of reasonable length (17.6 μ sec./in.). Alternatively, an electronic "storage tube," which works in a manner related to that of a television iconoscope can be used as a delay element.

As the applications of MTI (and subsequent pulse-Doppler radar) came into wider use in postwar years, many advances were made. For example, mercury delay lines were replaced by quartz types that have a better signal-to-noise characteristic, entail smaller losses per unit of delay time and are more stable than the mercury lines they replace.

4. Pulse-Doppler.—The development of pulse-Doppler (PD) radar types in the 1950s for specific military needs (e.g., ground surveillance) also made it possible to locate moving targets (distinguishing them from innumerable fixed objects on the ground and the resultant radar clutter) and to determine their range. CW emission is theoretically best for the discrimination of moving targets because of the frequency change, or Doppler effect, which is imparted to the reflected signals by the radial velocity of the target relative to the radar set. But since CW generators at centimetre wave lengths tend to lack adequate power output, and since CW does not of itself enable range measurement to be made (unless frequency-modulated, as in the radio altimeter), PD radar employs powerful pulse transmission that also effectively measures the distance to the target.

The PD system employs the Doppler shift phenomenon that occurs within the pulse reflected from a moving object and enables the moving object to be detected in a background of fixed echoes.

The Doppler shift that denotes target motion can be detected in either of two ways. One method, called coherent MTI (described above), involves maintaining a stable reference frequency at the transmitter-receiver set to beat with the Doppler-shifted frequency of echoes received from targets in motion. The other method, termed noncoherent MTI, is used in military surveillance radars. It depends upon the presence of echoes from fixed objects in the

same vicinity as the moving target under search. In this case the unchanged frequency of pulse-echo return from the fixed objects beats with the Doppler-shifted echo from the moving target to produce an aural or visual radar indication.

RADAR METEOROLOGY generally signifies the use of radar to observe and study the state of the atmosphere. It may be considered a division of radio meteorology, which also includes the study of the effects of the atmosphere on radio and radar propagation; i.e., bending and attenuation of electromagnetic waves. Radar meteorology comprises the study of radar echoes received from natural reflecting sources within the atmosphere and the relation of the echo characteristics to the nature of the atmospheric processes influencing the reflecting mediums. Some natural reflecting sources are hydrometeors (raindrops, cloud droplets, ice crystals and snowflakes), sharp invisible discontinuities in temperature and humidity, and the highly ionized paths of lightning discharges.

History.—The first verified report of a precipitation echo occurred on Feb. 20, 1941, when a 10-cm. wave length (3,000 mc. per second frequency) radar tracked a shower to a distance of seven miles off the English coast. Prior to that time the unavailability of the microwave magnetron restricted radar equipment to relatively low transmitted powers at the longer wave lengths. Under these conditions the relatively small precipitation particles could not be detected, although weak echoes were thought to be associated with storms as early as 1938 in England. The first detection of what are now believed to have been clear air echoes from the lower atmosphere was made by R. A. Watson-Watt, A. F. Wilkins and E. G. Bowen in England in 1935, using a 50-m. wave length pulsed system intended to explore the ionosphere. The earliest documented observation of lightning echoes was made by M. G. H. Ligda with a 10-cm. radar on July 20, 1949, in Cambridge, Mass. With the development of shorter wave length (1.25 cm.) radars toward the end of World War II, it became possible to detect some of the larger particles in nearby nonprecipitating clouds, while the increasing use of radar throughout the world brought with it the more widespread detection of both clear air echoes and lightning discharges.

Theory.—The radar transmits extremely short pulses of electromagnetic energy in a well-defined beam which is aimed by a parabolic reflector. When the beam is directed toward precipitation, a small fraction of the energy is scattered, a small fraction is absorbed and the remainder is transmitted through to be scattered

FIG. 39.—PULSE-TO-PULSE CANCELLATION OF ECHO SIGNALS HAVING CONSTANT PHASE. (A) FOUR SUCCESSIVE SWEEPS OF AN A-SCOPE. (B) THE RESULT OF SUBTRACTING EACH SIGNAL FROM THE CORRESPONDING ONE ON THE SUCCEEDING PULSE

and absorbed by particles deeper in the storm. The portion of the energy which is scattered or reflected back to the radar is amplified and displayed on an indicator in a position relative to the origin. This position depends upon the time taken for the energy to travel the round path between radar and target at the speed of light. If the beam is held in a fixed direction, the echoes are usually displayed on an A-scope (*see RADAR: How Radar Works*) which shows their amplitude or intensity versus distance. If the beam is made to rotate in azimuth around a vertical axis, the echoes brighten a spot on a cathode-ray tube at a distance out from the centre (radar position) depending on the target range and at a direction determined by the direction of the beam. This display is known as the PPI scope or plan position indicator. Since energy is usually reflected from the entire depth of the storm, the geographical position and extent of precipitation may be mapped accurately on the PPI scope to ranges limited mainly by the earth's curvature. For example, a storm at a range of 200 mi. must extend above 20,000 ft. to be detectable above the radar horizon. With this restriction, the PPI display enables the meteorologist to watch the motion and development of precipitation areas. When the beam is made to scan in a vertical plane, the echoes are displayed on the range height indicator or RHI scope showing a vertical cross section of the storm. On this scope, the meteorologist determines the height and growth rate of the storm, and its physical nature such as snow or rain, in addition to other storm features.

When the wave length of the electromagnetic radiation is large with respect to the size of the scattering particle, the energy returned to the radar is given by the Rayleigh scattering law and is proportional to the 6th power of the particle diameter; *i.e.*, doubling the diameter of a drop increases the echo by a factor of 64. In addition, the echo power is inversely proportional to the 4th power of the wave length; *i.e.*, doubling the wave length decreases the echo by a factor of 16. Since a raindrop is roughly 100 times as large as a cloud droplet, its echo is about 1,000,000 times as strong as that from a cloud droplet. However, since there may be 1,000 times as many cloud drops as raindrops, the total rain echo is about 1,000 times as strong as that from a water droplet cloud. Cloud radars operate at wave lengths near 1 cm. while precipitation radars operate between 3 and 23 cm. Clouds comprised of ice crystals are more readily detected because the crystals are usually much larger than the cloud droplets.

Of course, at any instant the radar receives the energy scattered back from a large number of particles confined within a volume defined by the beam width and half the pulse length in space. This is called the pulse volume. A 1 μ sec. pulse intercepts a 492-ft. depth of precipitation while a 1° beam intercepts a width of about 9,200 ft. at a range of 100 mi. Since there are roughly 100 raindrops per cubic foot of air, an individual echo from such a range may include the energy scattered from about 4,000,000,000,000 (4×10^{12}) raindrops. At a particular instant, the drops may be so distributed as to cause their individual echoes to reinforce each other; at another time, their individual echoes may cancel each other. Because the drops change position with respect to each other as a result of wind shear and turbulence, the total echo received from such a group of particles fluctuates rapidly from one pulse to the next. However, since the drops are randomly distributed within the pulse volume, the average echo intensity over a number of pulses is the sum of those from the individual particles; *i.e.*, it is proportional to the sum of the 6th powers of the particle diameters. This quantity summed over a representative unit volume of space within the pulse volume has been designated by the symbol Z by radar meteorologists. When they measure the average echo power from a storm, they are interested in the Z or reflectivity factor of that storm.

For a small target such as an airplane, the incident and reflected energy both spread out and decrease in intensity as the square of the target range. Thus, the echo from such a target decreases as the 4th power of the range. However, storms usually intercept the entire area of the radar beam so that the total energy incident on it does not depend on its range; it is only the reflected power which decreases with distance. For this rea-

son, the average echo intensity from a storm decreases only as the square of its range, provided its reflectivity or Z remains constant.

Water drops scatter microwave radiation about five times as well as ice particles of the same mass because of their higher index of refraction. Therefore, when snowflakes begin to melt as they fall into warm air with temperature above 32° F., their echo suddenly increases by a factor of 5 over that of the dry snow above. When the particles melt completely, however, the resulting raindrops quickly begin to fall at an average of about five times as fast as the original snowflakes, decreasing the number of particles per unit volume and the echo intensity proportionally. This causes the echo from the melting particles to be about five times as strong as that from both the dry snow above and the completely melted raindrops below. The exact variation of echo intensity through the melting zone depends on a number of other factors. In any case, the echo intensification in that layer makes it appear as a horizontal "bright band" on the RHI scope. Such "bright bands" are characteristic of most widespread precipitation in temperate latitudes and indicates that the rain originates in the form of ice crystals aloft.

The storm reflectivity factor or Z has also been found to be related to the precipitation rate, R , in both snow and rain, and to the water content per unit volume in clouds. Although the exact relation between Z and R depends on the nature of the particle size distribution, and it is possible to have equal rainfall intensities comprised of a large number of small drops with small Z or a few large drops with large Z , under average conditions the storm Z as measured by the echo intensity can provide an estimate of the precipitation rate within a factor of about 2. If the echo intensity is averaged over long periods, the estimates of total rainfall can be made with greater accuracy. Since a calibrated radar can measure the average rainfall over an area approximately 50 mi. in radius (about 7,500 sq.mi.) with an accuracy comparable to that from a network of several hundred rain gauges, and can secure these data quickly, it has great value for flood warning purposes.

One of the facts which limits the use of radar for the quantitative measurement of distant rainfall is the attenuation of the radar energy by scattering and absorption in intervening rain. Attenuation reduces the echo power by an amount which is unknown or difficult to determine; the echo may then be a useless measure of rainfall. At wave lengths of 10 cm. and larger, the attenuation in normal rains is negligible, and such wave lengths are therefore preferable for quantitative measurements. As the wave length decreases below 10 cm., the losses due to both scattering and absorption increase so that 1-cm. wave length radars can only penetrate a few miles into moderately intense rains. Even at 3 cm., only the front edge of an intense rainstorm may be seen on the radar scope.

Attenuation in snow is due only to the scattering and is generally negligible except at the very short wave lengths and in the most intense snowstorms.

Echo Interpretation and Uses.—In addition to the measurement of average echo intensity, the radar meteorologist studies the rate of pulse-to-pulse fluctuation of the echoes as an indication of the turbulence and wind shear in a storm. This technique is believed to have promise in identifying severe storms and tornadoes since the violent winds move the particles about rapidly. Use is also made of circular polarization, a technique which permits the cancellation of echoes from spherical particles. Those echoes which are not canceled with circular polarization are due to large nonspherical raindrops and hailstones which also occur in violent storms, and to wet snowflakes in the melting layer. Aircraft echoes are also only slightly reduced by circular polarization. Such a radar can therefore detect aircraft when they might be obscured in the weather echoes on a linearly polarized radar.

The greatest use of weather radar is in the observation of the geometric structure and motion of clouds and storms. Widespread precipitation such as that associated with warm fronts in middle latitudes is generally seen on the PPI scope as a fairly uniform echo mass covering large areas of the scope. On the RHI, the

advance deck of alto-stratus clouds and evaporating precipitation lowers slowly as the storm centre approaches until snow or rain finally starts at the ground. On the PPI, some pattern may usually be discerned within the larger echo masses associated with trails of ice crystals released from occasional discrete cloud cells; these trails twist and turn as the ice crystals fall into layers of different wind velocity. On the RHI scope, the trails frequently take the form of hooklike cirrus clouds such as may be seen visually in the sky on a clear day. Their slope on the RHI and pattern on the PPI are helpful in determining the variation of winds with height.

While individual trails or small precipitation areas move with the winds at the heights of the cloud cells from which the precipitation is released, the entire region of precipitation echo moves with the velocity of the large-scale pressure pattern or storm system.

The precipitation echoes associated with a cold front most frequently take the form of lines of shower or thunderstorm cells several hundred miles long oriented along the front. Individual cells tend to move with the mean winds or those near the 10,000-ft. level, and may be less than 10 mi. in diameter, although some lines fail to show any separation. On the RHI, the echoes appear as tall vertical columns with sharply defined edges and tops which may become diffuse as the water particles are transformed to ice crystals and form the anvils of cumulo-nimbus clouds. Such storms do not display the "bright band" except in their decaying stages. Similar echoes are associated with isolated showers and thunderstorms on hot days when the atmosphere is unstable. Their severity may be indicated on the radar by their height, sometimes exceeding 50,000 ft., their rate of growth which may exceed 2,000 ft. per minute, their strong echo intensity due to large raindrops and hailstones, and an attenuation shadow cast on other storms behind (at the shorter wave lengths). Tornadoes have occasionally been identified by a figure-6-shaped tail extending out from the edge of a larger thunderstorm echo.

The PPI pattern of a hurricane shows a number of spiral bands each perhaps several hundred miles long and 20 mi. wide which spiral into the vicinity of the hurricane eye or pressure and wind minima. The centre of spiral is readily identified making it possible to pinpoint and track the "eye" by radar with an accuracy of about ± 7 mi.

In the tropics where the storms generally move slowly the spiral bands may be more like complete concentric rings; however, as they move into middle latitudes the major precipitation tends to occur in the forward right sector. The outer bands are comprised of individual shower cells, while the inner bands are more continuous and display the "bright band" near the melting level.

Echoes are also detected from sharp discontinuities in moisture and temperature without the presence of particulate matter. These echoes, unidentified in the early days of radar, are called "angels." Isolated angels occur under a wide range of conditions though preferably in a turbulent atmosphere when moist parcels of air rise through a relatively dry environment into the bases of cumulus-type clouds. Widespread angel echoes have also been observed from the sea breeze front.

At wave lengths of 10 cm. and longer, the highly ionized columns produced by lightning discharges may also be detected. However, since the ionized path dissipates rapidly, the radar beam must be directed at the lightning region just at the discharge time. Cloud-to-cloud lightning is more readily discernible on the scope because of its greater horizontal extent than the cloud-to-ground variety; also it tends to occur in the upper and weaker snow regions of the storm so that its echo is not so easily obscured by the more intense rain echoes. Lightning echoes as long as 100 mi. have been observed.

For more information on radar theory, terminology and equipment, see RADAR.

RADCLIFFE, ANN (née WARD) (1764-1823), was the chief exponent in England of the Gothic novel, a kind of fiction extremely popular in the late 18th and early 19th centuries, which, rejecting the restraint of the classical tradition, indulged the imagination and the emotions with fearful happenings, and characteristically exploited the effects of crumbling buildings, the mysterious past, foreign settings, and the apparent or actual supernatural.

She was born in London on July 9, 1764. In 1787 she married William Radcliffe, a journalist and, later, proprietor of the *Morning Chronicle*, who encouraged her literary pursuits. Mrs. Radcliffe led a retired life, and the descriptions of French and Italian landscapes in her novels were based primarily on books and paintings. Her only journey abroad, to Holland and Germany, is described in *A Journey Made in the Summer of 1794* (1795).

Her first novels, *The Castles of Athlin and Dunbayne* (1789) and *A Sicilian Romance* (1790), were published anonymously. She achieved fame with *The Romance of the Forest* (1791). *The Mysteries of Udolpho* (1794), by which she became the most popular novelist in England, tells how the orphaned Emily St. Aubert is subjected to the cruelties of her aunt Mme Cheron and of Montoni, who marries Mme Cheron. Emily is separated from Valancourt, her lover, and, in an attempt to make her relinquish her fortune, is imprisoned first in Château-le-Blanc in Languedoc and then in the Castle of Udolpho in the Apennines. Strange and fearful occurrences take place in these castles which are all, however, ultimately explained. Emily escapes, and is finally reunited with Valancourt.

In *The Italian* (1797), Mrs. Radcliffe shows improved techniques of dialogue and characterization, and the plot is more tightly constructed. Vivaldi, a young Venetian nobleman, falls in love with Ellena de Rosalba, who is considered an unworthy match for him, and his mother conspires with Schedoni, a monk of massive physique and sinister disposition, to keep the lovers apart. Schedoni's personality overshadows the whole story. (His character influenced, among others, Byron in his concept of his heroes.) After various fearful adventures, Schedoni, about to murder Ellena, is led to believe from a locket round her neck that she is his daughter. Schedoni himself is revealed as a fratricide by the Inquisition, to which he has consigned Vivaldi, and the lovers are reunited. Mrs. Radcliffe's poems (1816) and her posthumous novel, *Gaston de Blondville* (1826), were comparatively unsuccessful. She died in London on Feb. 7, 1823.

In spite of their reputation as "tales of terror," there is little physical horror in Mrs. Radcliffe's novels, and, except in *Gaston de Blondville*, the apparently supernatural elements are finally explained away. Her characterization is usually weak, her historical insight almost nonexistent, and her plots abound in impossibilities. Her undoubted powers are revealed in her ability to create a limited but poetically intense world, seen through the sensibility of her heroines. She excels at intimating evil, maintaining suspense, evoking atmosphere, and varying her mood effects. It is this reliance on atmosphere rather than incident that distinguishes her from "Monk" Lewis (see LEWIS, MATTHEW GREGORY), although he was influenced by *The Mysteries of Udolpho*. The Gothic interest in ancient, decaying buildings informs her imaginative world, as do romanticized views of nature, in particular of woods, mountains, and lakes. She describes these in word pictures that reflect her delight in Romantic painting, and in that of Guido Reni. Her heroines, too, gain a spiritual consolation from nature that reminds one of Rousseau. Scott called Mrs. Radcliffe "the first poetess of romantic fiction," and her many admirers included Coleridge and Christina Rossetti. Writing in the tradition of the novel of sensibility, she boldly focused the

themes of nascent Romanticism in her stories, and paved the way for the greater talents of Scott and of the Romantic poets.

RADCLIFFE-BROWN, ALFRED REGINALD (1881–1955), British social anthropologist, whose major contribution was his systematic framework of concepts and generalizations relating to the social structures of simple societies, was born on Jan. 17, 1881, in Birmingham. After being educated at Trinity College, Cambridge, he took up the study of anthropology. In 1906 he went to the Andaman Islands, where his field work later won him a fellowship at Trinity College. In 1910 he carried out a second field expedition to Western Australia, concentrating on kinship and family organization. In 1916 he became director of education in the kingdom of Tonga and in 1921 took the chair of social anthropology at the University of Cape Town. In 1925 he accepted the chair of anthropology at Sydney University, where he built up a vigorous department for teaching, and for research in both theoretical and applied anthropology. A brilliant lecturer and conversationalist, he became a well-known personality in Australian intellectual circles in spite of a somewhat aloof and critical temperament. Between 1931 and 1937 he was professor of anthropology at the University of Chicago, after which he held the chair of social anthropology at Oxford until his retirement in 1946. Among many academic honours he received were the Rivers and Huxley Memorial Medals of the Royal Anthropological Institute, of which he was president in 1939–41. He died in London on Oct. 24, 1955.

Among Radcliffe-Brown's works are *The Andaman Islanders* (1922; new edition, 1948); *Social Organisation of Australian Tribes* (1931); *Structure and Function in Primitive Society* (1952); *A Natural Science of Society* (1957); and *Method in Social Anthropology* (1958).

RADCLIFFE COLLEGE, a liberal arts college for women in Cambridge, Mass., dating from 1879 and affiliated with Harvard University. While Radcliffe is separately incorporated and financed and has its own plant, the curriculum is identical with Harvard's and courses are conducted by the Harvard Faculty of Arts and Sciences under a plan of joint instruction. See **HARVARD UNIVERSITY**; see also **CAMBRIDGE (Mass.)**.

RADEGUNDA, SAINT (d. A.D. 587), a queen memorable for her religious foundations in Merovingian France, was a daughter of the Thuringian king Berthachar. She was brought up by her uncle Hermannfried (Irmfried), who had assassinated Berthachar in order to seize his possessions. Taken prisoner with her brothers by the Frankish kings (531), she was forced to marry one of her captors, Clotaire I (q.v.), in 536. Six years later one of her brothers was murdered; she took refuge at Noyon, where the bishop Medard consecrated her a deaconess. After residence at Saix (a property forming part of her dower), on the borders of Touraine and Poitou, Radegunda went to settle in Poitiers. There she founded the convent of Notre-Dame (c. 560). This was renamed Sainte-Croix when, in 568 or 569, some relics of the Holy Cross were deposited there. Radegunda built a church outside the walls of Poitiers to shelter the nuns' graves. For the convent, which had 200 nuns under the direction of the abbess Agnes, the queen adopted the Rule of St. Caesarius. The poet Venantius Fortunatus, who came to Poitiers in 567, celebrated Radegunda's merits; and Gregory of Tours was present at her obsequies, which took place on Aug. 13, 587.

See R. Aigrain, *Sainte Radegonde*, 2nd ed. (1952). (Jz. H.)

RADEK, KARL (1885–1939?), Soviet propagandist, and a notable victim of Stalin's purges, was born in Lwow (Lvov) in Galicia, of a Jewish family named Sobelsohn. Educated at the universities of Cracow and Bern, he became a member of the Social Democratic Party of Poland and Lithuania in 1901. Arrested during the revolution of 1905, he spent a year in a Russian prison. Subsequently he worked on the editorial staffs of left-wing Social

Democratic newspapers in Poland and later in Germany. During World War I, after some months of illegal antimilitarist activity in Germany, he established himself in Switzerland, where he wrote for the *Bern Tageblatt*. He took part in the Zimmerwald and Kienthal conferences (see **INTERNATIONAL, THE**) in September 1915 and April 1916. After the Russian Revolution of March 1917, he crossed Germany with Lenin on the way to Russia, but broke his journey in Sweden and stayed at Stockholm to issue a weekly bulletin on the Russian Revolution, in French and German, on behalf of the Russian Communist Party. After the revolution of November 1917, he joined the Communist Party and took part in the Brest-Litovsk peace negotiations. When the German revolution broke out in 1918 he made his way illegally to Germany. There, as a representative of the central committee of the Russian Communist Party, he was active in reorganizing the German Communist Party, working in its central committee after the murders of Karl Liebknecht and Rosa Luxemburg, but was imprisoned from February to December 1919. On his release he returned to Russia to become a leading member of the presidium of the Communist International. He returned illegally to Germany, however, and helped to organize the joint congress of German Communists and Left Independents. He was made a scapegoat for the German Communists' failure to seize power in autumn 1923; and, because of his support of the "right" groups of the German Communists, he lost his authority in the Communist International and his place in the Soviet Communist Party's central committee (1924). Expelled from the Communist Party as a Trotskyist in 1927, he was readmitted in 1930, and was a member of the editorial board of *Izvestia* from 1931 until 1936, when he was once again expelled from the party. In January 1937, Stalin had him tried with 16 others on a trumped-up charge of treason and sentenced to ten years' imprisonment. Radek must be presumed to have died in captivity. (L. B. Sc.)

RADETZKY, JOSEPH, GRAF (full surname **RADETZKY VON RADETZ**) (1766–1858), Austrian army officer, a military reformer whose victorious campaigns made him a national hero, was born at Trebnice, near Tabor, in Bohemia, on Nov. 2, 1766, of an old family of Hungarian extraction. Joining the Austrian Army in 1784, Radetzky became a first lieutenant in 1787. He served in the Turkish War of 1787–91 and later in the Low Countries in the first years of the French Revolutionary Wars (q.v.). From the first his courage and enterprise were conspicuous and, among other ventures, he led a successful cavalry raid near Fleurus, which penetrated behind the French lines. During the Italian campaigns of 1796–97 he took part under J. P. de Beaulieu and later under D. S. von Wurmser in operations against Napoleon Bonaparte. In 1805, with the rank of major general, he was given a command in Italy under the archduke Charles; and in 1809 he was fighting at Wagram with the rank of lieutenant field marshal. (See **NAPOLEONIC WARS**.)

In 1809 Radetzky became chief of the Austrian Army general staff and thus entered the field of politics and military policy. His efforts to remodel the Austrian forces on more efficient lines were frustrated by lack of funds, but nevertheless he succeeded in carrying out some essential measures of reorganization and in modernizing the tactical doctrine. In 1813, however, he left Vienna and went to the new army that was being formed in Bohemia, as chief of staff to Karl Philipp zu Schwarzenberg (q.v.). As such he had considerable influence in the councils of the Allies opposing Napoleon, particularly in planning the Leipzig campaign. He entered Paris with the Allied sovereigns and notables in March

BY COURTESY OF THE MUSEEN DER STADT WIEN
JOSEPH RADETSKY PHOTOGRAPHED
ABOUT 1855

1814 and accompanied them later to the Congress of Vienna. Returning to the army general staff, he tried for a time to reform the army further, but had no more success than before, and eventually resumed ordinary military duties. In 1829, by way of retirement, he was given the sinecure of governor of the fortress of Olmütz (Olomouc).

In 1831 Radetzky was again recalled to active service in Italy, at first nominally under J. P. von Frimont, but from December in supreme command himself. In 1836 he was made a field marshal.

The European revolutionary upheaval of 1848 found Austria unprepared, chiefly because Radetzky's advice had been neglected. Recalled for the last time, at the age of 82, he conducted the operations which ended in the victory of Novara on March 23, 1849 (see ITALIAN INDEPENDENCE, WARS OF). He was governor of Lombardy-Venetia from 1850 to 1857.

Radetzky was one of the most efficient and remarkable of the galaxy of central European professional soldiers of the troubled 18th and early 19th centuries. War was his only interest, and he had the attribute, not very common among Austrian generals, of being idolized by the rank and file; he was affectionately known as "Vater Radetzky." He died in Milan on Jan. 5, 1858.

See E. Schmahl, *Radetzky* (1938). (C. N. B.)

RADHAKRISHNAN, SARVEPALLI (1888–), Indian scholar and statesman, president of India 1962–67, was born of Telugu Brahman parents in Tiruttani, Chittoor district, Madras presidency (later in Andhra Pradesh), on Sept. 5, 1888. After being educated at the Madras Christian College, Radhakrishnan had a most distinguished scholastic career. His appointments included the professorship of philosophy at Mysore University (1918–21); the King George V professorship of philosophy at Calcutta University (1921–31 and 1937–41); the vice-chancellorship of Andhra University (1931–36); the Spalding professorship of eastern religions and ethics at Oxford University (1936–52); and the vice-chancellorship of Benares Hindu University (1939–48). From 1953 to 1962 he was chancellor of Delhi University. He delivered the Upton lectures at Oxford in 1926 and the Upton and Hibbert lectures in 1929. He also lectured extensively in the United States and China.

Radhakrishnan's written works include *Indian Philosophy*, two volumes (1923–27); *The Philosophy of the Upanishads* (1924); *An Idealist View of Life* (1932); *Eastern Religions and Western Thought* (1939); *East and West: Some Reflections* (1955). In both his lectures and his written works he has performed a notable service in interpreting Indian thought to the West.

From 1946 to 1952 Radhakrishnan was leader of the Indian delegation to the United Nations Educational, Scientific and Cultural Organization, being elected chairman of UNESCO's executive board for 1948–49. From 1949 to 1952 he served as Indian ambassador to the U.S.S.R. On his return in 1952 he took up his appointment as vice-president of the Republic of India. On May 11, 1962, he was elected president, succeeding Rajendra Prasad; in 1967 Radhakrishnan retired from politics, Zakir Husain succeeding. In his speeches, both as vice-president and as president, Radhakrishnan stressed the importance of creating a casteless and classless society in India, urging his countrymen to purge all thoughts of caste distinction from their minds.

See S. J. Samartha, *Introduction to Radhakrishnan: the Man and His Thought* (1964).

RADIAN MEASURE, a method for specifying the lengths of circular arcs. The circumference of a circle (*q.v.*) may be divided into 360 equal parts (degrees) and the length of an arc may be given by the number of degrees it contains; or the arc may be measured in units of length, for example inches; or, if different arcs of the same circle are involved, the radius may be used as unit of length. An arc with length equal to the circle radius is called the radian. The ratio of circle circumference to diameter (approximately 3.14) is denoted by π . Thus the circumference is 2π radii; *i.e.*, 360° equals 2π radians. One degree is

$\frac{\pi}{180}$ radians and one radian is $\frac{180}{\pi}$ degrees (slightly more than 57°).

To every angle formed by two radii of a circle there is a corresponding arc; and the ratio of such angles is the same as the ratio of corresponding arcs. It follows that arcs may be used to represent angles, and that angles may be measured in radians as well as degrees.

Often radian measure is preferable to degree measure. For instance, the ratio of a leg of a right triangle to the hypotenuse (the cosine of the angle adjacent to the leg) is approximately given by the expression $1 - \alpha^2/2$, where α is the radian measure of the angle; for an angle less than 30° the error is less than 1 in 375. A related advantage of radian measure is that it is the unique measure of angle such that the derivative (see CALCULUS, DIFFERENTIAL AND INTEGRAL) of the sine is the cosine. See also ANGLE; TRIGONOMETRY. (G. Y. R.)

RADIATION: BIOLOGICAL EFFECTS. All life is constantly being bombarded with various kinds of radiation—visible light, infrared, ultraviolet, radio waves, X-rays (from cosmic and terrestrial sources)—all of which are manifestations of energy transfer from one place to another. In a wide sense any consequence of the transfer of radiation energy to a living organism is a biological effect of radiation. This definition includes both the normal effects on many life processes (*e.g.*, photosynthesis in plants and vision in animals) and the abnormal or injurious effects resulting from the exposure of life to unusual types of radiation or to increased amounts of the radiations commonly encountered in nature. This article, devoted chiefly to the discussion of the deleterious effects of radiation, is divided into the following sections:

I. Definitions and Concepts

A. Types and Measurement of Radiation

1. Electromagnetic Waves
2. Particulate or Corpuscular Radiations
3. Measurement of Radiation

B. Mode of Action

1. Mechanisms of Energy Transfer
2. Ionization and Penetrating Power
3. Mechanisms of Biological Action

II. General Biological Effects

A. Genetic Effects

1. Gene Mutations
2. Chromosome Mutations
- B. Bodily (Somatic) Effects
1. Long-Term Effects
2. Short-Term Effects

III. Radiation and Human Health

A. Man's Radiation Burden

1. Natural Sources
2. Artificial Sources

B. Injury From Ionizing Radiations

1. Historical Background
2. Radiation Effects on Cells
3. Radiation Effects on Tissues and Organ Systems
4. Acute Lethal Effects
5. Exposure of the Embryo and Fetus
6. Protection Against External Radiation
7. Radioisotopes and Fallout
8. Studies on Human Populations
9. Cancer and Radiation

C. Effects of Hertzian Waves and Infrared Rays

1. Hertzian Waves
2. Infrared Rays

D. Effects of Visible and Ultraviolet Light

1. Intrinsic Action
2. Photodynamic Action
3. Effects on Development and Biological Rhythms
4. Effects on the Eyes

I. DEFINITIONS AND CONCEPTS

For a better understanding of the later sections of this article a review of the two main types of radiation—electromagnetic waves and moving atomic particles—their measurement, sources and mechanisms, is in order.

A. TYPES AND MEASUREMENT OF RADIATION

1. Electromagnetic Waves.—Energy can be transferred through matter or through space by means of oscillatory variations in electric and magnetic fields originating at various sources. Electromagnetic wave radiation is classified into several types, depending on frequency and wave length. The various types (in order of decreasing wave length and increasing frequency) and their

TABLE I.—*Electromagnetic Waves*

Wave type	Sources
Hertzian (Radio waves and Microwaves)	Radio transmitters
Infrared	Hot bodies
Visible	Hot bodies
Ultraviolet	Hot bodies; excited gases
X-rays and gamma rays*	Atoms struck by high-energy particles; radioactive materials; cosmic sources

*Similar to X-rays but emitted from the nuclei of some radioactive atoms.

sources are summarized in Table I.

2. Particulate or Corpuscular Radiations.—Simply speaking, an atom consists of a nucleus (composed chiefly of neutrons and protons) surrounded by a cloud of electrons; in addition there are other special particles. When separated, either by natural radioactive disintegration or by artificial means (as in a cyclotron, for example), these particles, charged or uncharged, are capable of transferring their energy, wholly or in part, to any substance through which they pass. Streams of such particles constitute particulate radiations. The more important types of particle, the magnitudes and signs of their charges (relative to that of an electron, defined as the unit negative charge), their masses (relative to the mass of a hydrogen nucleus, defined as the unit mass) and their main sources are summarized in Table II. The rate of transfer of energy by a particulate radiation depends on the mass of the particle, its velocity and, if charged, the magnitude of its charge.

TABLE II.—*Particulate Radiations*

Particle type	Charge	Mass	Sources
Electron*	-1	1/1843	Accelerating machines, radioactive materials
Proton†	1	1	Accelerating machines
Alpha (α) particle‡	2	4	Radioactive materials
Neutron	0	1	Nuclear reactors, accelerating machines

*Electrons emitted by radioactive nuclei are called beta (β) particles.

†Protons are the nuclei of hydrogen atoms.

‡Alpha particles are the nuclei of helium atoms.

3. Measurement of Radiation.—Radiation is detected and measured by various methods which rely on the property of the radiation to cause ionization in gases or emission of light from sensitive materials, or blackening of a photographic emulsion. Among the instruments used are the ionization chamber, the geiger counter and the scintillation counter.

Röntgen Unit.—The original biological unit of X- (or gamma) ray exposure, the roentgen unit (r), is defined as that quantity of radiation that produces a given number of charged ions in a given quantity of air under standard conditions.

Rad.—A more general and more accurately defined measure of local exposure to all types of radiation is the rad, the radiation dose absorbed in tissue itself. It is equal to 100 ergs per gram.

Rem.—The same dose in rad from different radiations may produce different degrees of biological effect. The dose in rem is the product of the dose in rad and a factor called the relative biological effectiveness (RBE) of the radiation used. The rem is taken to be that dose from any radiation which produces biological effects in man equivalent to 1 rad of X-rays.

For more technical definitions see RADIOLOGY. A detailed discussion of radioactivity may be found in RADIOACTIVITY.

B. MODE OF ACTION

1. Mechanisms of Energy Transfer.—There are several mechanisms by which energy is transferred from radiations to biological materials. Wave radiations yield up their energy through resonance. In general, the smaller a body, the higher its resonant frequency and therefore the higher the frequency of the radiation from which it will absorb energy. The energy of infrared and visible radiation is absorbed mainly by whole molecules and atoms and therefore appears mainly as heat. The energy of ultraviolet radiation is absorbed partly by the planetary electrons of atoms; an electron jumps to a higher-energy orbit, thereby bringing the atom into a state of excitation, in which it is chemically reactive. The energy of X-rays is also absorbed mainly by the planetary electrons of atoms, but the amount absorbed is usually great enough

to produce ionization; i.e., to induce an electron (or electrons) to escape altogether from the atom, thereby ionizing the atom; an ionized atom is highly reactive, even more so than one in a state of excitation.

Particulate radiations yield up their energy through collision with the planetary electrons or atomic nuclei of the material through which they pass. Charged particles usually react with the planetary electrons and therefore leave the atom in an excited or, more commonly, ionized state. Neutrons, being uncharged, are able to pass through the orbits of the planetary electrons and collide with the nucleus of an atom. The nucleus may then recoil, or it may capture the neutron. In biological material neutrons yield up most of their energy through collision with hydrogen nuclei, which recoil as hydrogen ions (i.e., protons). The neutron is eventually captured by some nucleus, and capture is usually followed by the ejection of one or more charged particles, often accompanied by a gamma ray.

2. Ionization and Penetrating Power.—Although all higher-energy radiations (i.e., X-rays and particulate radiations) produce ionization in biological material, the spatial distribution of the ionization depends on the type and penetrating power of the radiation, the nature of the material irradiated and the spatial distribution of the radiation source or sources. High-energy X-rays produce ionization that is rather sparsely but uniformly distributed along the track of the radiation; alpha particles cause intense ionization along their tracks; in between these come neutrons, protons and beta particles. In general, the lower the speed of a particle, the denser the ionization along its track, so that all particles tend to be more densely ionizing toward the ends of their tracks. High-energy X-rays penetrate deeply (X-rays commonly used in medicine are less penetrating), but most beta particles penetrate only a few millimetres in biological tissues and alpha particles only a small fraction of a millimetre. Animal tissues such as bone and teeth which contain elements of fairly high atomic weight, such as calcium, absorb much more energy from a given radiation than do soft tissues, which are composed mainly of elements of low atomic weight. Ultraviolet radiation is of very low penetrating power.

3. Mechanisms of Biological Action.—The biological effects of the higher-energy electromagnetic radiations and of all the particulate radiations are mediated through the ionization (and, to a lesser extent, the excitation) that they produce in biological tissue. Thus all ionizing radiations have broadly similar biological effects; such differences as are found are the result of differences in the spatial distribution of the ionization. Ionization in biological tissues is largely intracellular. Therefore, an explanation of its mode of action must be sought at the cellular level; effects on the whole organism are likely to be secondary. Two main types of intracellular action have been distinguished: first, direct action through ionization of biological structures along the ionized track; and second, indirect action through the formation of reactive chemical fragments (free radicals) that diffuse away from the ionized track and subsequently undergo further reaction elsewhere.

Direct Action.—Direct biological actions were studied in great detail in the period between 1927 and 1947. The leaders in this work included H. J. Muller in the U.S., N. Timofeeff-Ressovsky and K. G. Zimmer in Germany and D. E. Lea in Great Britain. A detailed quantitative theory was elaborated, the target theory or *Treffertheorie*, whereby a tissue undergoing irradiation was likened to a field traversed by the fire of a machine gun. It was supposed that to produce a given effect there must be one or more hits by an ionized track on a sensitive target, so that the probability of obtaining the effect was dependent on the probability of obtaining the requisite number of hits on the appropriate target. This theory was very successful in giving a quantitative treatment of many of the biological effects of radiations, particularly in the field of genetics.

Indirect Action.—In the field of radiation chemistry, where free radicals produced by radiation play a vital role as intermediates in chemical reactions, the target theory had little application, and from about 1940 the interest of radiation biologists tended to shift toward the indirect actions of radiations. This shift was given

impetus by the discovery in 1947, by J. M. Thoday and J. Read, that the induction of chromosome breakage, which had until then been viewed as a target-theory effect par excellence, was enhanced if the tension of oxygen was increased in the material irradiated. This led on to the discovery of protective substances, such as cysteamine and cysteine, which reduce some of the biological effects of radiation exposure; Z. Q. Bacq (Belgium) and H. M. Patt (U.S.) were leaders in this field. Many other studies followed in which it became apparent that, although there certainly were indirect actions of radiations, the distances over which indirect action could occur were always small, usually no more than a few microns.

II. GENERAL BIOLOGICAL EFFECTS

The biological effects of radiations may conveniently be subdivided into somatic effects—short-term somatic effects (*i.e.*, short-term effects on the body of the individual) and long-term somatic effects—and genetic effects. Historically, they were discovered in that order. But as the genetic effects are nearest to the cellular level, and the short-term somatic effects farthest from it, it is more convenient to consider them in the reverse order.

A. GENETIC EFFECTS

The genetic effects of radiations arise through damage to those intracellular bodies in the germ cells that are the material basis of heredity (*q.v.*). These are the chromosomes, with their constituent genes (*see* GENE). Genetic effects therefore occur only if the radiation reaches the germ cells. Thus in those animals (man is one) and plants in which the germ cells are fairly well covered by tissue, radiations of low penetrating power, such as ultraviolet light and alpha and beta particles, cannot produce genetic changes; however, radiations of high penetrating power, such as X-rays and gamma radiation, can induce genetic effects.

Radiation-induced genetic effects on animals and plants are probably not qualitatively different if consideration is given to the physiological variations between these two kinds of life. For obvious reasons, more research has been done on the changes induced in the genetic material of animals. Mutations induced by irradiation of seeds are of interest to plant breeders because of the possibility of producing new varieties. Differences have been found in the mutagenic effect of radiations on plants which appear to depend upon the density of ionization produced. Fast neutrons were found to be 10 to 100 times more mutagenic than X-rays. Radioactive elements taken up by plants can also be strongly mutagenic. In choosing a suitable dose for the production of mutations a compromise has to be reached between the mutagenic and damaging effect on the plants of the radiation. As the number of mutations increase so also does the extent of damage to the plant. A critical dose is defined which is that allowing 40% survival. In the irradiation of dry seeds by X-rays, doses of 10,000 to 20,000 r are usually given. Mutants can be produced by radiation that effects such properties as early ripening, resistance to disease, etc. Much of the work on the radiation breeding of plants has been carried out in Sweden and the U.S.S.R., and economically important varieties of various species have been produced.

In plants and animals genetic changes of two sorts are induced, namely gene mutations and chromosome mutations. They differ in important respects and will be considered separately.

1. Gene Mutations.—Radiation-induced gene mutations were first demonstrated by H. J. Muller in 1927. They are all of the same types that occur spontaneously in nature. Most gene mutations, whether spontaneous or radiation-induced, are harmful. They reduce the fitness of the organism in the sense that an individual carrying a mutated gene is less capable of surviving and leaving descendants than is an individual carrying the gene in its unmutated form. This is an empirical observation, but it may also be expected on theoretical grounds: any advantageous mutation that could occur spontaneously would probably have occurred at some time in the past and, being advantageous, would have spread through the species, thereby coming to represent the normal form of the gene; any mutation away from the normal form would therefore be a mutation to a less advantageous form.

GENETIC MUTATIONS IN FRUIT FLIES

These flies with abnormal wings are offspring of males that received internal radiation from radioactive phosphorus

Although the mutations induced by radiations are all of types that occur spontaneously, the relative frequencies with which any two particular genes mutate under irradiation may not be the same as the frequencies with which they mutate spontaneously; however, if whole classes of genes are considered, the mutational idiosyncrasies of particular genes are lost, and the over-all picture shows that exposure to radiation causes a proportionate increase in the mutation frequency of all classes of genes.

Experiments with animals and plants, notably by Muller and Timofeeff-Ressovsky and their co-workers, in the period between 1927 and 1935 established a number of factors influencing the induction of mutation by radiations. The yield of mutation is directly proportional to the amount of energy absorbed in the germ cells; *i.e.*, to the radiation dose. This linear dependence of mutation on dose, which is to be expected on target-theory considerations if gene mutation is the result of a single hit by an ionized track, has been demonstrated experimentally for doses down to a few r and is believed to be valid for all doses, though for statistical reasons it would be difficult to obtain experimental verification at doses much lower than this. The implication is that there is no threshold dose for the induction of gene mutation; *i.e.*, any dose, no matter how small, will induce some mutation.

Radiation intensity was originally thought to have no importance, the total amount of mutation induced being dependent only on the total accumulated dose. However, in 1958 it was shown by W. L. Russell that this does not hold good for mutation induced in immature germ cells (spermatogonia and oöcytes) of the mouse. The amount of mutation induced by a dose accumulated at a rate of about 1 r per day being only about a third of that induced by the same dose accumulated at about 100 r per minute. If this is true of mammalian spermatogonia and oöcytes generally, it holds important implications for man, whose germ cells are present mainly in the form of spermatogonia in the male and oöcytes in the female.

The amount of mutation induced by radiation is usually expressed in terms of the mutation-rate-doubling dose, which is the dose that induces as much mutation as occurs spontaneously in each generation. This is merely a mathematically convenient way of relating the amount of induced mutation to that arising spontaneously; there is no special biological significance in a mutation rate twice the spontaneous rate. The more sensitive the genes to radiation, the lower the doubling dose. Doubling doses for high-intensity exposure of several different organisms have been found experimentally to lie between about 30 r and 150 r; for seven specific genes in spermatogonia of the mouse the doubling dose is about 30 r for high-intensity exposure and about 100 r for low-

intensity exposure. Very little is known about the doubling dose for human genes: studies of the children of survivors of the atomic bomb explosions at Hiroshima and Nagasaki indicate that it must be higher than 10 r, but how much higher is not known; most geneticists assume that it is about the same as the doubling dose for the mouse.

The existence of a linear law relating induced gene mutation to radiation dose holds an important implication for populations: it implies that very small doses of radiation given to very large numbers of individuals may introduce into the population as many mutant genes as would be introduced through large doses to small numbers of individuals. Furthermore, it is necessary to take into consideration the probability that an exposed individual will contribute to the next generation at some time after exposure. It follows that exposure of individuals below reproductive age (including unborn fetuses) is genetically of the greatest importance, and exposure of those above reproductive age is of no importance.

The effect on a population of a rise in its mutation rate depends on the role played by mutation in determining the characteristics of the population. Deleterious genes enter the population through mutation but, because they reduce the fitness of their carriers, they tend to die out; thus a genetic equilibrium is set up at a point where the flow of deleterious genes into the population through mutation is counterbalanced by the loss through reduction in fitness. At equilibrium a constant fraction of the population will be handicapped by deleterious genes. Increasing the mutation rate would increase the gene-handicapped fraction proportionately. However, the full increase would not be manifest immediately; this would occur only when genetic equilibrium had again been established, which would probably require several generations.

2. Chromosome Mutations.—Ionizing radiations not only cause genes to mutate but also may break the chromosomes in which the genes are carried. Chromosome breaks often heal spontaneously, in which case no damage becomes apparent. If a break fails to heal, a germ cell may be formed that lacks an essential part of the gene complement; such a germ cell may be capable of taking part in the fertilization process, but the ensuing zygote is usually incapable of full development and dies in an embryonic state. When two chromosomes in the same nucleus are broken, it sometimes happens that the broken ends join together, but in such a way that the order of the genes in the chromosomes is changed; for example, part of chromosome A may join onto part of chromosome B and vice versa. A germ cell carrying such a chromosome structural change may be capable of giving rise to a zygote that may develop into an adult individual, but the germ cells produced by the latter include many that lack the normal chromosome complement and so give rise to zygotes that are incapable of full development. An individual of this sort is called semisterile, and the number of his descendants is correspondingly lower than normal. Chromosome structural changes therefore usually die out of a population; for this reason they are of little importance in human populations. In some species, however, there are mechanisms that reduce the loss of fertility usually associated with chromosomal changes, and in them such changes may be present in the majority of individuals. They include the evening primrose, *Oenothera*, and some species of the fruit fly *Drosophila*. As would be expected from target-theory considerations, the induction of two-break chromosome changes is not dependent on radiation dose in a simple linear fashion. High doses, and doses given at high intensities, induce proportionately more changes of this sort.

B. BODILY (SOMATIC) EFFECTS

Somatic effects due to radiation include all the injuries, long-term and short-term, to all the cells of the body of an organism—plant or animal.

1. Long-Term Effects.—Long-term somatic effects include damage to cells that are continually proliferating, so that the injury is passed on to succeeding cell generations. Such cells are found in embryonic tissues and in those tissues of the adult in which cell division normally continues throughout life; in vertebrates

these include the blood-forming tissues, the basal layer of the skin, the intestinal mucosa and, in the male, the germ cells. Furthermore, the radiation may affect the rate of cell division: the cells may be killed or otherwise rendered incapable of further division; division may be slowed down; or, conversely, tissues in which cell division normally ceases in the adult may escape their normal biological control and cell division may continue. Mosaic sectors have been observed in many organisms exposed to radiations during embryonic development. They include humans who have been exposed *in utero* during diagnostic examination of the mother; in some fetuses there was a brown sector in the otherwise blue iris of an eye; in others there was a black patch in an otherwise blond head of hair. Unilateral and nonheritable expression of a congenital defect of a type that is normally bilateral and heritable is also believed to arise sometimes through somatic mutation. Sometimes the mutant region includes some of the germ cells, and the genetically mutant nature of the mosaicism can then be confirmed by a breeding test.

Slowing down or suppression of cell division, including radiation-induced cell death, may have important end results where embryonic tissues are exposed. This is because the rate of cell division is not uniform throughout an embryo; at any one stage of development the cells in some parts will be dividing rapidly, while in other parts there will be relatively little cell division. Exposure to radiation will affect the rapidly dividing tissues more strongly than the others, with the result that the pattern of development will be distorted and the individual, when adult, will have disproportionate parts. This phenomenon, which is well known in experimental plants and animals, is also known in man. (Among the persons exposed as early embryos to the atomic bomb radiations in Japan were a number with abnormally small heads and mental defect. Such children have also occurred following exposure *in utero* to medical X-rays.)

Radiation exposure of the blood-forming tissues leads to a reduction of cell division and therefore to a reduction in the blood-cell count which may, if sufficiently great, amount to clinically recognizable anemia (for this reason regular blood-cell counts used to be carried out on all radiation workers). Radiation exposure of the germinal tissues likewise leads to a reduction of cell division, which may be sufficient, if the dose is large enough, to induce sterility; a dose of 200 r to the gonads of the human male induces temporary sterility, lasting a few months; a gonad dose of about

BY COURTESY OF BROOKHAVEN NATIONAL LABORATORY

SOMATIC MUTATION IN DAHLIA

White petals on a normally red flower caused by daily exposure to gamma radiation

500 r to either sex induces permanent sterility. Opacity of the lens of the eye, which may develop into a full cataract, has been observed following exposure to ionizing radiation, especially neutrons.

A further long-term effect of radiation exposure is a general shortening of the life span, not associated with death attributable to any specific cause. It is a phenomenon well established in laboratory animals, but evidence about its extent in humans is conflicting; the mechanism, whether through gene mutation in somatic cells, a reduction of cell division or some other cause, has not been established.

Loss of biological control over cell division, *i.e.*, the induction of cancer in animals and distortion of parts in plants, is one of the more serious long-term somatic effects of excessive radiation exposure. It may occur in any tissue. Cancer of the skin was the first long-term effect to be observed; it may result from exposure to ultraviolet as well as to ionizing radiation.

The nature of the dependence of the long-term effects of radiation on radiation dose, type and intensity is not yet established with certainty. Many authorities assume that the relationship is of a nonthreshold type, meaning that any additional exposure increases the probability of long-term effects occurring. It is a characteristic of the induction of cancer that there may be a long period of time between the causal exposure and the appearance of the effect: for some skin cancers in man induction periods of 40 years have been recorded.

2. Short-Term Effects.—A sufficiently large dose of radiation will kill any organism, but the dose required varies greatly from species to species; mammals are killed by less than 1,000 r, but fruit flies may survive 100,000 r, and many bacteria and viruses even higher doses.

This lethal action of radiation can be used as an alternative to heat treatment for sterilizing materials such as surgical sutures. It has found little application in the sterilization of foodstuffs, mainly because the high doses required induce chemical changes in the food that render it unpalatable. (T. C. CA.; Jo. C. O.)

III. RADIATION AND HUMAN HEALTH

A. MAN'S RADIATION BURDEN

1. Natural Sources.—Throughout the ages man has been exposed to what is called natural background radiation. This includes radiation from cosmic as well as terrestrial sources. It has probably played the major role in evolution of life by providing mutations upon which natural selection has acted.

TABLE III.—Cosmic Radiation Exposure

Location	Mean dose in rads per year
Sea level, temperate zone	0.020 to 0.040
5,000 feet	0.040 to 0.060
10,000 feet	0.080 to 0.120
40,000 feet	2.8
30 km 600 km.	7-15
600 km 60,000 km.	15-1500*
single solar flare	1-1000*

*From protons, assuming that electrons are shielded out.

Cosmic rays (*q.v.*) rain down incessantly on the earth's atmosphere. Interacting with atoms in the air, such rays resolve themselves into various components—chiefly penetrating electrons, gamma rays and mesons (a class of atomic particles)—by the time they reach the earth. There is considerable variation in the intensity of cosmic radiation, both geographically and temporally, since sun spots and solar flares influence the primary intensity. For about every 5,000 ft. of altitude the intensity approximately doubles (*see* Table III). (Posing an obstacle to man's space travel is a belt of "trapped" radiation that surrounds the earth at a height of several thousand miles [*see* VAN ALLEN RADIATION BELTS].)

Man also receives external and internal radiation from natural radioisotopes, particularly radium and its daughters, members of the thorium series, potassium-40, carbon-14 and hydrogen-3 (tritium). The last two are produced by cosmic rays. The greater part of external radiation comes from the radioactivity of minerals, whereas radioactive contamination of drinking water and

food plays an integral part internally. Drinking waters vary by a factor of 10,000 in their radioactivity content. Among the foods, radium content of nuts and cereals is higher than that of milk or meat. Internal doses in normal persons from natural radioactivity are listed in Table IV.

TABLE IV.—Internal Dose Due to Natural Radioactivity

Isotope	Radioactivity in curies	Radiation	Dose in rads per year	Critical organ
Carbon-14	9×10^{-10} per g	Beta rays	0.0016	Gonads
Potassium-40	10.4×10^{-10} per g	Beta rays	0.0165	Gonads
Potassium-40	1.15×10^{-10} per g	Gamma rays	0.0023	Gonads
Radium and daughters	1×10^{-10} in body	Alpha, beta gamma rays	0.0380	Bones

2. Artificial Sources.—Since the discovery of radioactivity, man has substantially added to his natural radiation load. Medical X-rays and radioisotopes are often necessary for the diagnosis or treatment of disease. In some countries almost the entire population is exposed to periodic diagnostic X-rays and a significant fraction to therapeutic doses. Therapeutic doses vary widely depending on, among other things, the disease being treated. Routine diagnostic doses, though they may vary somewhat depending on the apparatus and the operator, usually fall within certain limits (*see* Table V). High-voltage power supplies for radar or television, X-ray machines in shoe stores, dental X-rays, luminous dial watches and phonograph static eliminators frequently give significant doses of radiation, sometimes more than is warranted. Fur-

TABLE V.—Typical Doses Received in Routine X-ray Diagnosis

Examination	Dose per exposure
Chest X-ray	0.04-1 rad
Gastrointestinal X-ray	1 rad
Extremities	0.25-1 rad
Fluoroscopy	10-20 rads per minute
X-ray movie	25 rads per examination

ther contributions of man that have become of considerable concern are fallout, the radioactive debris proceeding from atomic explosions, and nuclear testing.

B. INJURY FROM IONIZING RADIATIONS

Although all forms of radiation, if intense enough, may produce some adverse effects on man, the "hard" or penetrating ionizing rays, including X-rays and moving atomic particles, present the greatest hazard. Paradoxically, these same ionizing rays, when judiciously used in medicine, constitute a formidable weapon against cancer and an invaluable aid in diagnosis (*see* RADIOLOGY).

The concept of maximum permissible exposure to radiation is a much-debated point, subject to change as more information accumulates. Although the body may not be noticeably affected, genetic damage may occur and pass unnoticed for several generations, as was mentioned earlier. Maximum permissible exposures are proposed for persons who, by the nature of their work, are exposed to amounts of radiation beyond that to which the general population is exposed. (Recommendations vary somewhat in different countries; those given in Table VI are for the U.S.)

The limiting factor for persons in the general population is based on the genetical hazard. The greater worldwide concern for these

TABLE VI.—Maximum Permissible Exposures to Ionizing Radiations for Professional Radiation Workers

Organ exposed	Exposure in rem
Whole body	3 rem in 13 weeks
Professional emergency dose (once in life)	25 rem
Accumulated dose under 18 years	No professional exposure permitted
Accumulated dose over 18 years	Average of 5 rem per year
	less than 15 rem in any single year
Skin	8-10 rem in 13 weeks or 30 rem per year
Gonads	5 rem per year
Bone	10 rem in 13 weeks or 30 rem per year

heritable, non-threshold types of radiation damage is expressed in the recommendation of the International Commission on Radiological Protection: for individuals not engaged in radiation work the exposure to ionizing radiation should not exceed 5 rem in a lifetime, in addition to natural background radiation and to the

lowest practical dosages from medical exposures.

1. Historical Background.—In Dec. 1895 the German physicist Wilhelm Conrad Röntgen demonstrated the first X-ray pictures, among them that of the left hand of Mrs. Röntgen. Within a few weeks the news of the discovery spread throughout the world, and the penetrating properties of the rays were soon exploited for medical diagnosis without immediate realization of possible deleterious effects. The first reports of X-ray injury to various human tissues and to vision came from the Italian F. Battelli (1896). In that same year Elihu Thomson, the physicist, deliberately exposed one of his fingers to X-rays and provided accurate scientific observations on the development of roentgen-ray burns.

Also in 1896 Thomas Alva Edison discovered "fluoroscopy"; he was engaged in developing a fluorescent roentgen-ray lamp when he noticed that his assistant, Clarence Dally, was "poisonously affected" by the new rays so that his hair fell out and his scalp became inflamed and ulcerated. By 1904 Dally developed severe ulcers on both hands and arms; these lesions, which soon afterward became cancerous, caused his early death. During the next few decades many investigators and medical doctors developed radiation burns and cancer, and more than 100 persons died, presumably as a result of their exposure to X-rays. These sad early experiences eventually led to an awareness of radiation hazards for professional workers and stimulated development of a new branch of science, radiobiology.

Radiations from radioactive materials were not immediately recognized as being related to X-rays. In 1906 A. H. Becquerel, the French physicist and discoverer of radioactivity (1896), accidentally burned himself by carrying radioactive material in his pocket. Noting this, Pierre Curie, the co-discoverer of radium, deliberately produced a similar burn on himself. A few months later it was found that radium could be useful in medicine; this discovery led to the founding of the Radium hospital in Paris in 1906. It was soon recognized, however, that radium could also be very toxic. Beginning about 1925 a number of women in the painting industry who were exposed to luminescent paint containing radium became ill with anemia and lesions of the jawbones and mouth; some of these persons later developed bone cancer. The same thing happened to some patients who had received radium internally to relieve arthritis and other diseases. In the 1930s H. S. Martland and others called attention to these radium hazards and the practices were stopped.

In 1933 Ernest Lawrence and his collaborators completed the first full-scale cyclotron, at Berkeley, Calif. This machine was a copious source of the neutron rays that had at that time just been discovered by Sir James Chadwick, in England. This time, however, human guinea pigs were spared. Ernest, his brother John Lawrence and Paul Aebersold exposed rats to the beam of the cyclotron; they found that fast neutron radiation was about 2½ times more effective in killing power than were X-rays. These facts indicated the need for protection for investigators engaged in research with the cyclotron; thus a form of shielding was devised for the machine. When the first atomic reactor, built in Chicago, proved Enrico Fermi's principle of self-sustaining fission chain reactions (1942), considerable knowledge of the biological effects of neutrons was already available.

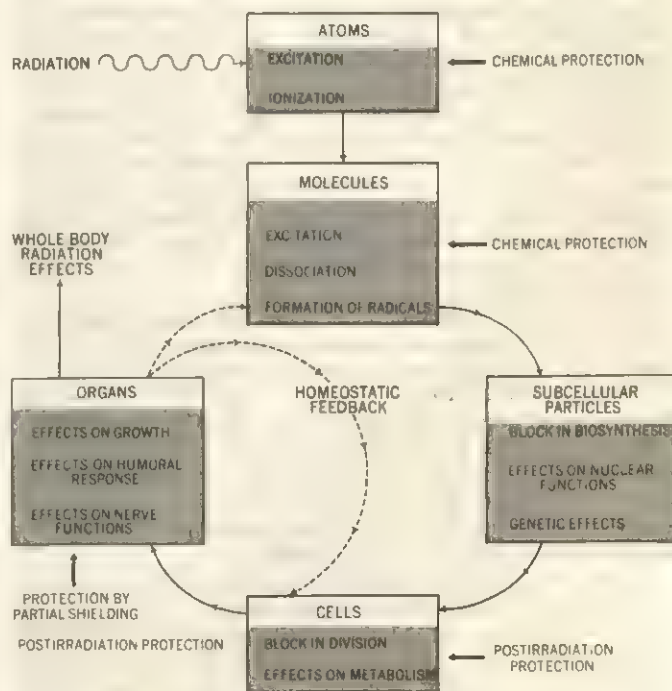

Modern accelerators produce a wealth of different types of radiations, including leptons (electrons, positrons, muons and neutrinos) and hadrons. There are more than 100 known baryons and about 60 known mesons, each with different interaction properties. In addition, since the advent of space flight, the effects of certain space radiations on man became of interest. Protons in the Van Allen Radiation Belts and protons and heavier ions in solar flares and near the top of the atmosphere are of particular importance. To meet the problems presented by these advances, health physics (including radiation shielding and health protection) has become an elaborate discipline.

2. Radiation Effects on Cells.—To understand radiation effects it is necessary to study the cellular and subcellular events that succeed a radiation insult and that give rise to gross effects. The work done in this area has already contributed a great deal to the

understanding of normal and diseased states. How radiation may inflict biological damage is shown in the accompanying diagram.

The radiosensitivity of individual human cells in culture was first measured by T. T. Puck, in the 1950s. He used the progeny of human cervical cancer cells (of the strain named HeLa) kept alive in tissue culture. HeLa and other available human cells are so sensitive to radiation that half of them are killed by doses of 80 to 300 rem. The killing effect manifests itself primarily when the cells attempt to divide but cannot do so since their chromosomes are broken and abnormally jointed as a result of radiation. Neuroblasts (nerve cell initials) and cells of the intestinal epithelium, of mucous membrane and of blood-forming organs exhibit the greatest sensitivity. Rapidly proliferating tissues of the reproductive system are particularly sensitive to radiation. Oakberg demonstrated that spermatozoa in the mouse can be killed by a few roentgens. Given time, however, reproductive organs recover fully from sublethal doses of radiation. Most resistant are adult nerve cells, which owe their resistance to the fact that they do not normally divide; specialized nerve endings and synapses (e.g., in the retina), however, may exhibit great radiosensitivity. At sublethal doses human cells exhibit delay of cell division following radiation, perhaps as a consequence of a block in the synthesis of new genetic material (deoxyribonucleic acid or DNA), while the synthesis of proteins goes on. Such cells frequently turn into "giants," having several hundred times normal volume. Late effects, e.g., the initiation of cancerous growth, may have their origin in sublethally injured cells and are in part due to genetic and chromosomal alterations.

Cellular radiation effects are the complex result of breakage and rejoining of chromosomes. In some lower organisms, for example bacteriophage, we know that X-rays cause the scission of both strands of the DNA molecule in order to cause lethal effect. In the larger and more complex mammalian cells chromosome breakage might also be the result of radiation-induced release of nuclease enzymes. Chromosome breakage may be followed by normal or abnormal rejoining of the broken ends. Mortimer Elkind has shown in the late 1950's that there are mechanisms available in mammalian cells that can repair sublethal injury. Thus, the final effect is dose-rate dependent and is less at low dose rates.

GENERAL SCHEME OF EVENTS IN RADIATION ACTION

Radiation acts on atoms, which in turn cause modification in molecules, cells and organs as shown. The existence of homeostatic regulation in the human body causes highly complex "feedback" interactions. The levels at which various protective agents act are also shown.

3. Radiation Effects on Tissues and Organ Systems.—

Since tissues are composed of cells, tissue effects reflect the lethal and sublethal changes in the cells. These initiate a complex defense pattern: cells injured by radiation may release toxic substances; e.g., proteolytic enzymes and nucleases which are able to inflict further injury. The injury is often followed by a regeneration accomplished by increased rate of cell division: the sick cells are often lysed and removed, and if recovery is not complete, scar tissue may form.

Inhibition of epithelial tissues with cellular breakdown and increased permeability leads to invasion by pathogens, inflammation, ulceration, loss of fluids, nausea and diarrhea.

Inhibition of blood formation leads, in the course of days or weeks, to leukopenia (reduction in the number of white cells), which lessens defense against infection; anemia (reduction in the number of red cells), which results in defective oxygen transport; lassitude; anoxia (reduction of oxygen in tissue); bleeding, due to a failure of platelet synthesis; and loss of immunity. None of these effects is as yet completely understood by medical science.

It is known that, because of the varied cellular effects of radiation, the function of individual organs can become imbalanced. Since the body has widespread humoral and neuronal interconnections, irradiation of a single organ can modify the functions of the rest of the body. For example, George de Hevesy demonstrated in 1945 that radiation of the spleen and liver causes retardation of nucleic acid synthesis elsewhere in the body. Another example of this effect is given by irradiation studies on the pituitary of animals and humans, as shown by C. A. Tobias and others. Pituitary irradiation can arrest the growth of a young animal and can affect his sexual development and metabolism. In humans irradiation of the pituitary can arrest proliferation of certain hormone-dependent cancer cells, thereby causing regression of this type of cancer wherever it may be located in the body.

Radiation effects due to whole-body radiation can be lessened by the shielding of particular parts of the body. L. O. Jacobsen and others demonstrated in mice that shielding of part of the blood-forming system, e.g., the spleen, increases the radiation tolerance by a factor close to two. Shielding of other parts of the body also protects, but to a lesser extent. Least protection is afforded by head shielding.

Some investigators claim a chronic deterioration of the central nervous system from moderate dose levels (although others have shown in experiments with monkeys that radiation doses up to lethal levels do not impair learning ability).

Generally speaking, man does not sense a moderate radiation field, though X-rays do produce "phosphene," a light sensation on the dark-adapted retina. Studying the behaviour of rats, Kimmeldorf found that in some food preference tests, animals, when given a choice, will avoid radiation fields of even a few roentgens. Others have shown that three roentgens, probably acting on the olfactory system, are sufficient to arouse a slumbering rat, and a few roentgens can accelerate seizures in mice genetically susceptible to these.

In man and other mammals the retina and smooth muscle respond to intense pulses of radiation; the cornea and peripheral nerves require much higher dose rates to respond.

4. Acute Lethal Effects.—Prior to Aug. 6, 1945, there was no known case of widespread loss of human life due to penetrating radiation. On that day the first atom bomb used in warfare was exploded over Hiroshima, causing the death of about 66,000 persons, many of whom died of the effects of radiation. In persons exposed to very large doses of radiation painful, ugly and repulsive symptoms occur prior to a delayed death.

In the lethal radiation syndrome the greater the dose given, the sooner and more profound the radiation effects. Following a single dose of 400–800 rem to the whole body, survival is improbable. Very high doses, 5,000 rem or more, cause immediate and discernible effects on the central nervous system. States of intermittent stupor and incoherence vary with hyperexcitability resembling epileptic seizures. Death is certain within several days. This syndrome has been carefully studied in animals; a human case has been described by S. G. Wilson (see *Bibliography*).

When the dose is between 600 and 1,000 rem, the earliest symptoms are loss of appetite, nausea and vomiting, followed by prostration, watery and bloody diarrhea, abhorrence of food, and fever. The blood-forming tissues are profoundly affected, and in 15 to 30 days the white blood cell count may decrease from about 8,000 per mm.³ to as low as 200 per mm.³. The body loses its defenses against microbial infection, and inflammation of mucous membranes and intestinal lining may occur. As a result of the reduction in blood platelets the blood loses its ability to clot, and spontaneous internal or external bleeding may result. Return of the early symptoms, often accompanied by delirium or coma, presages death. There can be great individual variation in the symptoms. At lower doses they may be delayed for a few days. Complete loss of hair within ten days has been taken as an indication of the lethal severity of the exposure.

In the dose range 150 to 600 rem survival is possible (though in the upper range improbable), and the symptoms appear as above, but in milder form and generally following some delay. Nausea, vomiting and malaise may begin on the first day, then disappear, and a latent period of relative well-being follow. Anemia and leukopenia set in gradually. After three weeks internal hemorrhages may occur in almost any part of the body, but particularly in mucous membranes. Susceptibility to infection remains a very great hazard, and some loss of hair occurs. Weight loss, lassitude, emaciation and fever may last for many weeks before recovery or death occurs.

Moderate doses of radiation can interfere seriously with the immunity mechanism. In animals this manifests itself in enhanced sensitivity to bacterial toxins, greatly decreased fixation of antigens, and reduced efficiency of formation of antibodies. Furthermore, antibiotics, unfortunately, appear to have reduced effectiveness in combating postirradiation infections. In the 1960s plastic isolators became available that allow antiseptic isolation of a person from his environment and may thus protect him from infection from external sources in a period critical for his recovery.

Man is generally able to survive a single dose of less than 150 rem. The symptoms are similar to those already described, but milder and delayed. In doses under 100 rem the discernible radiation effects may be so slight that the exposed person is able to continue his normal occupation though there is a measurable depression of his bone marrow. Sublethal doses may have chronic sequelae many years later.

5. Exposure of the Embryo and Fetus.—Most of the information on effects of radiation in the human embryo has been based on results of studies on laboratory animals. From these data it has been concluded that babies, children and the aged are somewhat more sensitive to radiation than is the adult. In the embryo (the first eight weeks of pregnancy) radiosensitivity is greatest. Radiation delivered to the embryo can lead to miscarriage or stillbirth. Exposure of the fetus (eight weeks to birth) can lead to congenital malformations, stunted growth and premature aging. The embryo and the fetus are probably several times more radiosensitive than is the adult.

The developing nervous system is particularly sensitive, and even a relatively mild dose of radiation may have discernible effects, particularly on the brain. Pathological studies by S. P. Hicks (U.S.) have shown this in great detail. M. N. Livanov and his associates (U.S.S.R.) demonstrated the stunted development of the central nervous system using studies on induced reflexes. Brain abnormalities found in radiation exposed mice include microcephalus (unnaturally small brain), exocephalus (brain continues to grow outside of skull) and hydrocephalus (abnormally large skull due to intracranial pressure).

6. Protection Against External Radiation.—Great efforts have been made by scientists of many countries to find agents that will increase radioresistance of the body.

The findings by H. G. Crabtree and W. Cramer in 1933 that living systems deprived of oxygen are more radioresistant, and by A. Lacassagne in 1942 that newborn rats kept in carbon dioxide atmospheres were twice as resistant as their litter mates kept in air, went largely unnoticed until 1950. In that year H. M. Patt demonstrated that large doses of the amino acid cysteine given prior to

irradiation provided substantial protection against radiation effect. Following this discovery many substances were found with some protective action. Although the matter is still under debate, it appears that many of these substances act by producing anoxia or by competing for oxygen with normal cell constituents and radiation-produced radicals. Since anoxia is in itself a highly hazardous physiological state and all protective compounds tried thus far are toxic, it cannot be said that protection of humans by these drugs prior to radiation exposure is a practical matter.

TABLE VII.—Some Chemical Protectors Effective in Mice or Rats

Class	Specific chemical	Effective dose milligram/kilogram tissue
Sulfur compounds . . .	Glutathione	1,000
	Cysteine	1,000
	Cysteamine	150
	AET*	350
Hormones	Estradiolbenzoate	12
	ACTH	25 for 7 days
Enzyme inhibitors. . .	Sodium cyanide	5
	Carbon monoxide	by inhalation
	Mercaptoethylamine (MEA)	235
	Para-aminopropiophenone (PAPP)	30
Metabolites	Formic acid	90
Vasoconstrictors . . .	Serotonin	50
Nervous system drugs .	Amphetamine	1
	Chlorpromazine	20

*Aminoethylisothiuronium bromide hydrobromide.

Beginning with 1961 some diurnal changes in the radiosensitivity of rodents were reported—an indication that the complex humoral factors responsible for daily rhythms also alter the response of tissues to radiation.

On the other hand a few classes of substances are known that render animals more sensitive to acute radiation effects. Compounds that sensitize mice or rats to radiation include: thyroxine, methylandrostenediol, synkavite, porphyrins, beta-homocysteine, thioethanol, 3,4-benzopyrene and monoiodoacetic acid. Perhaps the most interesting of these is the hormone thyroxine, a normal secretion of the body. A large class of sensitizers at the cellular level include nucleic acid analogs (e.g., 5-fluoro-uracil).

It may appear from the foregoing that acute radiation syndrome in mammals is the result of complex interaction from many affected organ systems. Nevertheless, it was shown in the early 1960s that there is some genetic control of radiosensitivity, since susceptible and resistant mouse strains were developed. Inability of recovery of the hemopoietic (blood-forming) system appears to be linked with high radiation sensitivity.

Beginning with the 1950s the Lobund Laboratories of Notre Dame University, which pioneered in the study of germfree animals, has shown that germfree mice that spend their entire life in a sterile environment exhibit greater resistance to radiation than do animals in a normal environment, no doubt due in part to elimination of the hazards of infection.

In 1965 John B. Little and R. S. Chang of Harvard university reported a type of transformation of human cells that increased their radioresistance 1,000 fold. First, multiplication of normal cells is inhibited by about 500 rad; then the cells are transformed by infection with a *lipovirus*. After this treatment more than 500,000 rad is required to produce a similar inhibition effect on cell multiplication.

For many years it was held that cure of radiation disease was hopeless since events were thought to be irreversible once a person had received a lethal dose. It was historically important, therefore, when E. Lorenz and L. O. Jacobsen demonstrated in mice that ground substance of embryo, spleen or bone marrow administered following irradiation allowed the animals to survive what would otherwise be a lethal dose of X-rays. It is hoped that detailed study of this finding will lead to the understanding of various physiological processes.

It has been shown that most of the effect of transfused bone marrow depends on the provision of intact, living cells, which then migrate to the marrow of the irradiated host and proliferate there, repopulating the host's marrow with cells characteristic of the donor. Bone marrow transfusion between animals of different strains is successful in these cases because the irradiated

animal loses its ability to develop antibodies against the injected "foreign" tissue. If the injected bone marrow proliferates rapidly enough, it may save the host from acute lethal effects of radiation.

Mammals that carry successful grafts of bone marrow become "chimeras," i.e., organisms producing cells of more than one genotype. Several months later the transplanted tissue may develop a disease sometimes called "wasting disease" (or homologous disease). This is an immune reaction between the proliferating donor cells and the irradiated host and is often rapidly fatal.

If bone marrow could be taken with ease (as blood is taken) from various normal human volunteers, cultured and preserved under refrigeration, then injected only into immunologically compatible individuals, it might prove to be a powerful therapeutic agent against radiation disease. Transfusion of fresh normal human bone marrow has already demonstrated some worth in alleviating radiation effects. In 1958 an unfortunate accident occurred at a nuclear reactor in Yugoslavia in which five persons were exposed to near lethal doses of mixed neutron and gamma radiation. They were flown to the Radium hospital in Paris, where four of them received human bone marrow transfusions. As judged by their recovery, several of these men were considerably benefited.

Bone marrow transfusion, as well as transplantation of other organs, may be of importance in future control of various seemingly incurable conditions; e.g., leukemia and some types of anemia. A special radiation technique has been applied in conjunction with bone marrow transfusion in some very desperate cases. Leukemia patients, usually in the terminal stages of their disease, first receive a whole body "lethal" dose of X-rays or some other form of radiation. This is presumed to kill all the cells in the marrow, including the leukemic ones. Somewhat later, compatible normal bone marrow is injected to repopulate the patient's bone marrow with normal cells of the donor, thus ending the leukemic condition. Initial attempts to treat leukemia in this fashion have been generally discouraging, possibly because bone marrow transplants of this type have only rarely been successful. The clue to successful bone marrow transplantation is the complete understanding of the genetical and biochemical aspects of immunological compatibility. Only when this knowledge is attained will transplantation of bone marrow (and also of essential organs such as the kidney) become established as a feasible medical practice.

7. Radioisotopes and Fallout.—Radioactive isotopes usually emit electrons or positrons, alpha particles and/or gamma rays, or even characteristic X-rays. The exposure may be external, in which case penetration is an important factor. Alpha particles do not penetrate deeply enough in the skin to cause damage. Beta particles or X-rays over 30 kv. can be hazardous to the skin, causing redness, loss of hair or ulceration. Large doses may cause skin cancer.

Isotopes can also enter the body by ingestion, inhalation or injection. Their radiation effects then depend on their internal distribution, duration of retention in the body, energies and rate of radioactive decay (half-life or half-value period). The problem is enormously complicated since isotopes have different and sometimes elaborate distribution patterns.

The definition "critical organ" has been assigned to that part of the body that is most vulnerable to a given isotope. The critical

TABLE VIII.—Maximum Permissible Concentration (MPC) of Some Radioisotopes

Isotope	Chemical form	Critical organ	Microcuries in body
Tritium (Hydrogen-3)	Water		2,000
Carbon-14	Carbon dioxide		400
*Strontium-90	Water soluble salt	bone	40
Iodine-131	Water soluble	thyroid	50

WHOLE BODY COUNTING ROOM (THICK METAL WALL BETWEEN SUBJECT AND RECORDING APPARATUS CUT AWAY)

The scanning head (cylinder above model) can distinguish the whole spectrum of gamma-ray emitting radioisotopes to determine the radioisotopic content of the subject's body

organ for plutonium, radium, strontium and many other fission products is bone and the adjacent bone marrow. For soluble fission products (and also some forms of uranium), which will distribute in the entire body, the critical organs are the gonads or sometimes the kidneys. For iodine the critical organ is the thyroid gland. Insoluble air-borne radioactive dust often deposits in the alveoli of lungs, while colloidal particles of very small size can reach the bone marrow, liver or spleen. Table VIII is an abbreviated list of the maximum permissible concentrations (U.S. recommendations) for man of some radioisotopes. (Maximum permissible concentration is the greatest amount of a radioisotope that can be accumulated in the body without producing noticeable damaging effects. Compare with maximum permissible dose, which is applicable to radiation received from external sources [see *Studies on Human Populations*].)

Since isotopes continuously deliver radiations to the surrounding tissue, one must distinguish between the effect of protracted continuous exposure and single acute or periodically repeated exposures. For beta, gamma and X-radiations, utilizing split dose delivery, it has been found that 15% to 40% of an acute radiation effect "disappears" within several hours; the body is, therefore, able to tolerate a greater total dose when the dose is protracted or when part of it is given at later times. For neutron and alpha radiation the recovery is less. (Neutrons are generally more effective than X-rays: for acute effects, by a factor of 1 to 8; for long-term effects of chronic radiation, by a factor up to 25.)

Fallout is the deposition of air-borne radioactive contamination on the earth. Radioisotopes may be produced naturally in the air by cosmic radiation or may enter the air from stack gases of atomic reactors following industrial accidents or from bombs or bomb tests. After 1954 bomb tests carried out by several nations produced fallout measurable on the surface of the entire world, arousing great attention and controversy with respect to its health and genetic effects. It is within the realm of practical feasibility to cover a significant portion of the earth's surface with fallout in time of war. While much of the bomb hazard is due to blast waves and heat, the radiation dose from fission products could be so intense that only persons remaining in underground shelters for some weeks could hope to survive such an attack. Usually the most prominent isotopes in fallout are fission products; however, all materials exposed to nuclear bombs may become radioactive.

Several of the radioisotopes contained in fallout are especially hazardous because they remain radioactive for relatively long periods (have long half-lives). Cesium-137 and strontium-90 may be the most important (see *FALLOUT*). On the ground, fallout material can cover external surfaces and foliage and later be washed into the soil, whence plants incorporate strontium-90 along with the chemically similar calcium, and cesium-137 with potassium. Persons obtain these radioactive materials mostly from drinking water and from plant and animal foods, including milk. In the sea much of these materials can eventually lodge in the bodies or skeletons of fishes and in plants near the coast.

Strontium-90 becomes concentrated in bone and remains there in steadily decreasing amounts for almost 30 years, producing local irradiation. Its actual concentration within the body is difficult to measure because of the softness of its rays. There is generally lower concentration of strontium-90 in man than in other animals or in plants or soil. Newborn babies, who have actively growing bones, retain relatively greater amounts of strontium-90 than do older persons.

The most easily detectable fallout product in animals and in man is iodine-131; this isotope emits beta and gamma rays and is enriched about 100 times in the thyroid gland through selective accumulation. Because of its relatively short half-life, 8 days, iodine-131 is probably not the most hazardous fallout isotope. But if a large population is affected by excessive amounts, radiations from this isotope could lead to metabolic disturbances and increased thyroid cancer incidence, especially in children.

Methods that have been developed for biological protection from fallout extend from efforts for keeping isotopes out of the body to biochemical means for rapid elimination of isotopes from tissues. Airborne radioactive particles may be kept from the lungs by masks having suitable filters. Ingested isotopes may be prevented from being absorbed in the intestinal tract by certain mucoprotein substances that show great surface affinity for adsorption of strontium and other substances. In 1964 Canadian investigators demonstrated that sodium alginate prepared from certain brown seaweed called kelp is particularly useful in this regard. It is possible to remove virtually all radioactive strontium from cow's milk without affecting the essential nutritive components. Certain chelates (for example EDTA, ethylenediaminetetraacetic acid) will react with strontium and "cover" this atom. As a result, when EDTA is present in the blood, deposition of strontium in bones is reduced (elimination of already deposited isotopes is also somewhat accelerated). Most chelating agents are not specific for strontium; unfortunately, they also chelate the closely related and important element calcium, an undesirable feature.

8. Studies on Human Populations.—Several groups of persons have been exposed to large amounts of radiation. Among these are the survivors of the atomic bombings of Hiroshima and Nagasaki, and some Marshallese and Americans exposed on Rongelap and neighbouring islands in the course of atomic bomb tests. In the former group the incidences of leukemia and cataracts are higher than in the general population. Fertility seems somewhat reduced and life span possibly shortened.

Hundreds of persons have a measurable radium burden in their bodies. Many of them received the radium as a method of treatment for arthritis and other diseases in the early 1930s. By the use of modern counting methods the amount entrapped in the body of this long-lived alpha-particle-emitting isotope (half-life of over 1,500 years) may be determined and may eventually provide accurate information on the dose that can cause bone cancer.

Certain groups of persons receive considerable doses of X-rays during radiation therapy for various ailments. In England a survey indicated the late results of X-ray therapy to the lumbar spine of persons having ankylosing spondylitis (a rheumatic ailment). The incidence of leukemias and bone tumours among these patients was higher than that of the general population. In a separate study suggestive evidence was obtained that children of women given abdominal X-rays for diagnostic purposes during pregnancy may develop more leukemia than children whose mothers were not so X-rayed. Children who received X-irradiation to the thymus at

an early age appeared to show greater than normal incidence of cancer and leukemia in subsequent years. As a result of these studies it seems prudent to limit radiation exposure for children

TABLE IX.—*External Dose Due to Natural Radioactivity*

Source	Dose in rads per year
Ordinary regions	0.025-0.160
Active regions	
Granite in France	0.180-0.350
Houses in Sweden (Alum shale)	0.158-0.220
Monazite alluvial deposits in Brazil	Mean 0.500 max 1.0
Monazite sands, Kerala, India	0.47-2.8

and embryos as much as possible. Practices such as X-raying feet in shoe stores seem completely unwarranted. Attempts should be made to reduce the numbers of necessary exposures received in dental X-rays, in fluoroscopy, in chest X-ray procedures and in diagnosis with radioisotopes.

The possible effect of radiation on radiologists is a much debated question. An earlier study in the United States indicated that their life span may be several years shorter than that of other doctors and that they have more leukemia and more stillborn children. However, no significant differences were found between English radiologists and their colleagues.

Localities with higher radium content seem generally to have more congenital malformations, though radiation as a direct cause has not always been established. In Jachymov, Czech., where for many generations miners have mined radioactive ore, lung cancer is quite prevalent; though the radioactive ore is undoubtedly involved, genetic factors (due to inbreeding) and silicosis of the lungs from inert ore may also be partly responsible for this high incidence of cancer. In Sweden many persons are constantly exposed to comparatively high radiation background due to the uranium in the building blocks of their houses.

An entire segment of the coast-line state of Kerala, India, is composed of radioactive monazite sands. Since the inhabitants and their ancestors have lived in this same locality for many generations, India, with the help of the United Nations, has initiated a study of the possible harmful effects of this long-term radiation exposure by comparing the health of this population segment with another group living on uncontaminated soil nearby. Preliminary studies have not revealed any differences in disease patterns or longevity between these two populations.

As mentioned earlier, radiation with its deleterious effects causes a person to become "physiologically" older than his actual age would indicate. Using mortality studies of survivors of the Hiroshima blast, it appears that where very large doses are absorbed, each rem received by the whole body physiologically ages a person 2 to 15 days. Statistical fluctuations, however, are very great and experimental results difficult to interpret. It is not yet known whether this concept of aging holds for doses smaller than 50 rem or for protracted radiation exposure. On the other hand, at least three different sets of experiments on mice have indicated that there is a small increase in life span in animals chronically exposed to very low levels of radiation (of the order of 0.1 rem per day).

There are several concepts of the nature of radiation-induced aging. One theory maintains that all disease experiences from early childhood, as well as toxic factors in the environment, act together to determine the physiological age of an individual. According to this model, the fallout radiation hazard currently is much less of an aging factor than cigarette smoking, lack of exercise, obesity, or childhood diseases. Another concept, one more specific to radiation injury, states: the aging effect produced by radiation is due to the number of irreversible chromosome aberrations produced in the somatic (tissue) cells of mammals. Many of the chromosome aberrations can be demonstrated in blood cells or in liver cells several months following exposure to radiation, and chromosome aberrations have generally been associated with impaired cellular function. Neither of these theories has thus far been able to account fully for the modifying effects of the homeostatic system controlled by organs regulating the elaboration of hormones.

Some remarkably sensitive techniques were developed to mea-

sure radiation-induced chromosome aberrations in human blood and bone marrow. Such aberrations have persisted in irradiated populations for a span of some years following radiation exposure. For example, survivors of the Hiroshima atomic blast carried a few unusual configurations of chromosomes in their cells for more than 20 years.

Since radiation at high dose levels has definite effects on longevity, malignant disease and reproduction, one may speculate on the effects of radiation on the entire human population. In the early 1950s it was believed that a 25-rem dose could double the mutation rate in the human population; since most of these mutations are "bad," genetic effects should limit the "permissible dose" for the whole population. More recently W. B. Russell has shown that in mice at low dose rate, mutation induction is reduced by a factor of about four; other experiments in rats and in the fruit fly also failed to show the full scale of deleterious genetic effects expected in populations. Considerations on genetic effects must also include the possibility that mutations induced allow accelerated evolutionary adaptation to changing factors in the environment.

9. Cancer and Radiation.—The role of large doses of radiation in increasing the incidence of cancer and leukemia cannot be questioned. It has been demonstrated in all animal species tested thus far. Studies on animal populations have indicated that the onset of cancer can be delayed by many years following radiation exposure and that protracted radiation exposure is more carcinogenic than single exposures. Initially, radiation may produce precancerous lesions in the cells of the body, but it may take some additional factors to turn those lesions into malignant tumors.

It is interesting to note that radiation-induced leukemia in certain strains of mice can later be propagated to other members of the mouse population by a virus factor. It appears that the role of radiation in this instance might be to activate a leukemia virus already present in mice. In some forms of cancer and leukemia, characteristic chromosome aberrations have been observed. It is not known, however, whether these aberrations are a cause or a result of the disease. Generally speaking, the increased cancer incidence in irradiated populations parallels the radiation-induced aging and may be a manifestation of the older physiological age of the irradiated individuals.

It is possible that exposure of the whole human population, even to minute doses in fallout, may lead to some thousands of new leukemia and cancer cases in the world. Thus far the data do not clearly demonstrate whether leukemia (or cancer) incidence is strictly proportional to dose or whether a "threshold" dose level exists below which carcinogenic effects are negligibly small. In order to acquire adequate data, a population of several million would have to be studied for several years.

There is a large school emphasizing that all good studies of the origin of cancer point to a number of factors, including genetic, hormonal and injurious factors (chemical or virus), that must act together before cancer is produced. The great majority of cancer and leukemia cases in the earth's population is probably not caused by radiation but by other agents.

See also CANCER; LEUKEMIA.

C. EFFECTS OF HERTZIAN WAVES AND INFRARED RAYS

1. Hertzian Waves.—The effects of Hertzian waves (electromagnetic waves, radio waves and microwaves or radar waves) and of infrared rays are usually regarded as equivalent to the effect produced by heating. The longer radio waves induce chiefly thermal agitation of molecules and excitation of molecular rotations, while infrared rays excite vibrational modes of large molecules and release fluorescent emission as well as heat. Both types of radiation are preferentially absorbed by fats containing unsaturated carbon chains.

Nikola Tesla in 1891 was the first to record the fact that heat production resulted from bombardment of tissue with high-frequency alternating current (wave lengths somewhat longer than the longest radio waves) and to point out the possibility of its utilization for medical purposes. At the same time J. A. d'Arsonval, using the same current, began to experiment on animals and

human beings. In 1898 R. von Zeyneck used high-frequency current to produce heat within the organism, and was followed in this by Von Berudt and other workers. To this form of treatment F. Nagelschmidt applied the term "diathermy." This method of internal heating is beneficial for relieving muscle soreness and sprain. Diathermy can be harmful, however, if so much internal heat is given that the normal cells of the body suffer irreversible damage. Since man has heat receptors primarily in his skin, he cannot be forewarned by pain when he gets a deep burn from diathermy. Sensitive regions easily damaged by diathermy are those having reduced blood circulation; e.g., bone or the lens of the eye. Cataracts of the eye lens have been produced in animals by microwave radiation applied in sufficient intensity to cause thermal denaturation of the lens protein.

In the radio-television industry and in the radar divisions of the military, persons are sometimes exposed to high-energy densities of microwave radiation. The hazard is particularly pronounced with exposure to microwaves from "masers," capable of generating very high intensities of microwaves. For occupational exposure, tolerance levels that have been set in the U.S. are summarized in Table X.

The heating effect of high-frequency waves and currents has had some use in surgery. The first surgical use of short waves (8 megacycles) was made by L. H. Stiebock, who successfully destroyed a patient's tonsils without the necessity of giving an anesthetic. This procedure produces cutting by heat coagulation of tissue without producing bleeding. It has been used to cut certain structures (e.g., the dura membranes) in brain surgery and in minor skin operations. Higher-frequency electromagnetic waves (about 10 megacycles) are also used in brain surgery for producing "heat lesions" in the treatment of Parkinson's disease and cerebral palsy.

TABLE X.—Maximum Permissible Exposures to Microwave Radiation

Frequency (megacycles)	Part exposed	Single exposure level (watts/cm. ²)	Continuous exposure level (watts/cm. ²)
1,000-3,000	Whole body	0.3	0.01
3,000	Eye	17	0.15
3,000	Testes	1.3	0.005

Such heat lesions produced in certain parts of the brain may temporarily relieve the tremors accompanying these diseases.

2. Infrared Rays.—An important part of solar energy reaches the earth in the form of infrared rays. Absorption and emission by the human body of these rays plays an important part in temperature exchange and regulation of the human body. Principles of infrared emission and absorption must be considered in design of air conditioning and of clothing.

Overdosage of infrared radiation, usually resulting from direct exposure to a hot object (including heating lamps) or flame, can cause severe burns ("flame burns"). While infrared exposure is a hazard near any fire, it is particularly dangerous in the course of atomic chain reactions. In the course of an atomic detonation a brief but very intense emission of infrared occurs together with visible and ultraviolet light emitted from the fireball ("flash burns"). Of the total energy of nuclear explosion, as much as one-third may be in the form of thermal radiation, moving with the velocity of light (186,000 mi. per second). The rays will arrive almost instantaneously at regions removed from the source by only a few miles. Smoke or fog can effectively scatter or absorb the infrared components, and even thin clothing can greatly reduce the severity of burn effects. (See also BURNS.)

D. EFFECTS OF VISIBLE AND ULTRAVIOLET LIGHT

Life could not exist on earth without light from the sun. Plants utilize the energy of the sun's rays in the process of photosynthesis to produce carbohydrates and proteins, which serve as basic organic sources of food and energy for animals. Light is a powerful regulating influence on many biological systems (see ANIMAL BEHAVIOUR: *Sensory Capacities of Animals*; PLANTS AND PLANT SCIENCE: *Plant Movements: Tropisms*; PHOTOPERIODISM; PHOTOSYNTHESIS). Most of the strong ultraviolet rays of the sun, which are hazardous, are effectively absorbed by the upper atmosphere.

At high altitudes and near the equator the ultraviolet intensity is greater than at sea level or at northern latitudes. Light pulses from lasers are comparable in intensity to direct, unattenuated rays from the sun. A single pulse, less than a microsecond long, can cause severe burns, kill cells, and denature protein molecules.

Very short-wave ultraviolet light, below 2,200 Å, is highly toxic for cells; in the intermediate range the greatest killing effectiveness on cells is at about 2,600 Å (1 Å = 1/10,000,000 mm.). The nucleic acids of the cell, of which the genetic material is composed, strongly absorb rays in this region. This wave length, easily available in mercury vapour, xenon or hydrogen arc lamps, has great effectiveness for germicidal purification of the air.

Since penetration of visible and ultraviolet light in body tissues is small, only the effects of light on skin and on the visual apparatus are of consequence. When incident light exerts its action on the skin without additional external predisposing factors, scientists speak of intrinsic action. In contrast, a number of chemical or biological agents may condition the skin for action of light; these latter phenomena are grouped under photodynamic action. Visible light, when administered following lethal doses of ultraviolet, is capable of causing recovery of the cells exposed. This phenomenon, termed "photorecovery," has led to the discovery of enzyme systems capable of restoring damaged nucleic acids in genes to their normal form. It is probable that photorecovery mechanisms are continually operative in some plants exposed to direct action of sunlight.

There is some evidence to indicate that not only overall light intensity but spectral compositions also have differential effects on organisms. For example, in pumpkins red light favours the production of pistillate flowers and blue light leads to development of staminate flowers. The ratio of females to males in guppies is increased by red light. Red light also appears to accelerate the rate of proliferation of some tumours in special strains of mice. The intensity of incident light has an influence on the development of light-sensing organs: the eyes of primates reared in complete darkness are much retarded in development.

1. Intrinsic Action.—Light is essential to man because of its biosynthetic action. Ultraviolet light induces the conversion of ergosterol and other vitamin precursors present in normal skin to vitamin D, an essential factor for normal calcium deposition in growing bones. While some ultraviolet light appears desirable for formation of vitamin D, an excess amount is deleterious. Man has a delicate adaptive mechanism that regulates light exposure of the more sensitive deeper layers of his skin. The transmission of light depends on the thickness of the upper layers of the skin and on the degree of skin pigmentation. All persons except albinos are born with varying amounts of melanin pigment in their skins. Exposure to light further enhances the pigmentation already present and can induce production of new pigment granules. N. R. Finsen of Denmark realized the therapeutic possibilities of sunlight and ultraviolet light around 1900. He was an exponent of the idea that exposure of the whole body to sunlight promotes health.

The French physician J. M. Charcot in 1858 was the first to recognize that large doses of ultraviolet radiation caused "sunburn." The wave length of about 2,800 Å is most effective. It induces reddening and swelling of the skin (due to dilation of the blood vessels), usually accompanied by pain. In the course of recovery epidermal cells are proliferated, melanin is secreted and the outer corneal layer of dead cells is thickened.

G. Findlay in 1928 was the first to clearly show that prolonged or repeated exposure to ultraviolet light leads to the delayed development of skin cancer. The fact that ultraviolet light, like X-radiation, is mutagenic (induces mutations) may explain its ability to cause skin cancer, but the detailed mechanism of cancer induction is not yet completely understood. There seems very little doubt, however, that skin cancer in man is in some cases correlated with prolonged exposure to large doses of sunlight. Among coloured persons who are protected by rich melanin formation and thickened corneal structure of the skin, incidence of cancer of the skin is several times less frequent than it is among white people living at the same latitude.

2. Photodynamic Action.—There are a number of diseases in

man and animals in which light sensitivity is involved; for example, hydroa, which manifests itself in blisters on parts of the body exposed to sunlight. It has been suggested that this disease is due to a light-sensitive porphyrin compound found in the blood.

Actually there are many organic substances and various materials of biological origin that make cells sensitive to light. When eosin is added to a suspension of human red blood corpuscles exposed to light, the red corpuscles will break up in a process named hemolysis. Other typical photodynamic substances are rose bengal, hematoporphyrin and phyloerythrin. All these are dyes capable of fluorescence. Their toxicity manifests itself only in the presence of light and oxygen.

Some diseases in domestic animals result from ingestion of plants having photodynamic pigments. For example, St. Johns-wort's disease is caused by the plant *Hypericum*. Fagopyrism results from eating buckwheat. In geeldikopp (yellow thick head) the photodynamic agent is produced in the animal's own intestinal tract from chlorophyll derived from plants. In humans the heritable condition of porphyria is frequently associated with light sensitivity, as are a number of somewhat ill-defined dermatological conditions that result from exposure to sunlight. The recessively inherited rare disease xeroderma pigmentosum is also associated with light exposure; it usually results in death at an early age from tumours of the skin developing on exposed areas. Certain drugs (e.g., sulfanilamide) sensitize some persons to sunlight. Many cases are known in which ingestion of or skin contact with a photodynamic substance was followed by increased light sensitivity.

3. Effects on Development and Biological Rhythms.—In addition to its photosynthetic effect, light exerts an influence on growth and spatial orientation of plants. This phototropism is associated with yellow pigments and is particularly marked in blue light. The presence of illumination is a profound modifier of the cellular activities in plants as well. For example, while some species of blue-green algae carry out photosynthesis in the presence of light, they do not undergo cell division.

Diffuse sensitivity to light exists also in several phyla of animals. Many protozoans react to light. Chameleons, frogs and octopuses change colour under the influence of light. Such changes are ascribed to special organs known as chromatophores, which are under the influence of the nervous system or endocrine system. The breeding habits and migration of some birds are set in motion by small consecutive changes in the daily cycle of light.

Light is an important controlling agent of recurrent daily physiological alterations (circadian rhythms) in many animals and probably man (see RHYTHMS, BIOLOGICAL). Lighting cycles have been shown to be important in regulating several types of endocrine function: the daily variation in light intensity keeps the secretion of adrenal steroids in synchrony; the annual breeding cycles in many mammals and birds appears to be regulated by light. Ambient light somehow influences the secretions of a tiny gland, the pineal body, located near the cerebellum. The pineal body, under the action of enzymes, produces melatonin, which in higher concentrations slows down the estrus cycle; low levels of melatonin, caused by exposure of animals to light, accelerates estrus. It is believed that light stimulates the retina, and information is then transmitted by sympathetic nerves to the pineal body.

4. Effects on the Eyes.—The wave length of light that produces sunburn can also cause inflammation of the cornea of the eye. This is what occurs in "snow blindness" or after exposure to strong ultraviolet light sources. Unusual sensitivities have been reported. Ultraviolet light, like infrared or penetrating radiations, can also cause cataract of the eye lens, a condition characterized by denatured protein in the fibrous cells forming the lens. The retina is usually not reached by ultraviolet light, but large doses of visible and infrared can irreversibly bleach the visual pigments, as in "sun blindness." Numerous pathological conditions of the eye are accompanied by abnormal light sensitivity and pain, photophobia. The pain appears to be associated with reflex movements of the iris and reflex dilation of the blood vessels of the conjunctiva. Workers exposed to ultraviolet light sources or to atomic flashes should wear protective glasses.

Since the eye lens and the vitreous humour are relatively trans-

parent to visible radiation, it is possible to cause lesions on the retina directly by focused laser beams, sources of intense infrared and visible light energy (see LASER). The effect is a microburn, causing coagulation of retinal tissue; such photocoagulation has been used to "weld" detached retinas. Management of intraocular tumours has also been attempted by local applications of laser beams; there is some hope that laser beams can be useful in destroying deep-lying tumours as well.

RADIATION BALANCE OF THE EARTH: see METEOROLOGY: *Solar and Terrestrial Radiation: Heat-Balance and the Field of Temperature of the Atmosphere.*

RADIC, STJEPAN (1871–1928), Croatian peasant leader and a firm advocate of self-government for his country, was born on July 11, 1871, at Trebarjevo. Impulsive and dynamic, he was in trouble for his nationalist outbursts while still a student at Zagreb. After travels in Bohemia and Russia and studies in political science in Paris, he worked as a journalist and became editor of the Zagreb newspaper *Hrvatska Misao* in 1902. With his brother Ante, he organized the Croatian Peasant Party in 1904. This party advocated Slav solidarity and the predominance of the

peasantry in Croatian politics, claiming that the peasantry preserved the national individuality through its numerical and economic strength and its cultural and moral values.

In March 1918, having ceased to believe in a federalist reorganization of Austro-Hungary, Radic began to cooperate actively with the National Council in Zagreb for the establishment of a Yugoslav union (see YUGOSLAVIA: History). Yet he was against hasty unification and demanded equal rights for Croats and Serbs and the recognition of Croatia's traditional autonomy. Disagreement with the Belgrade regime led to his imprisonment in 1919–20. In the general election of 1920 the majority of the Croats voted for his party, but the only result for him was a long period of sterile opposition, during which his party's boycott of parliamentary proceedings enabled Nikola Pasic in 1921 to give the first Yugoslav constitution a centralist and unitary character. In July 1923 Radic went to Paris, London, and Moscow to seek support for a Croatian peasant republic. Greatly disappointed by the indifference of the Western powers, he returned to Zagreb in August 1924 and was imprisoned. In March 1925, however, his nephew Pavle Radic effected a reconciliation with the government; and Radic himself was released in July. Accepting the constitution, he entered the government as minister of education in November 1925, but returned to opposition in 1927. Then, with Svetozar Pribicevic, a Serbian Democratic leader, he formed the peasant-democratic alliance which demanded a federalist reorganization of Yugoslavia. During a heated debate in the national assembly on June 20, 1928, the Serbian deputy Punisa Radic shot Radic and several of his political friends. Radic died of his wounds on Aug. 8, 1928.

(A. S. PA.)

RADICAL, one who desires extreme change of part or all of the social order. The word (Lat. *radix*, "root") was first used in a political sense in England, and its introduction is generally ascribed to Charles James Fox, who in 1797 declared for a "radical reform" consisting of a drastic expansion of the franchise to the point of universal manhood suffrage. The term radical thereafter began to be used as a general term covering all those who supported the movement for parliamentary reform. After the passage of the Reform Act of 1832, which extended the suffrage only to part of the middle class, a group of Radicals allied with the Whig faction in parliament continued to press for an extension of the vote to include even the working class. When the Reform Act of 1867 further widened suffrage, the Radicals, notably in London and Birmingham, took the lead in organizing the new voters, helping to transform the Whig parliamentary faction into the Liberal Party of the later Victorian era. Because of their efforts on behalf of the working-class vote the Radicals earned the loyalty of the trade unions; from 1874 to 1892 every trade unionist who sat in Parliament regarded himself as a Radical.

In France before 1848, the term radical designated a republican or supporter of universal manhood suffrage; the open advocacy of republicanism being technically illegal, republicans usually called themselves radicals. After 1869, a self-styled Radical faction led by Georges Clemenceau began to drift away from the moderate democratic-republicanism of Léon Gambetta. These Radicals regarded themselves as the true heirs of the French Revolutionary tradition. In 1881 at Montmartre they adopted a platform calling for a wide range of social reforms, and at the turn of the century the Radical-Socialist Party (*q.v.*) was formed.

The English Radicals of the 19th century were influenced by philosophical ideas assuming that men are able to control their social environment by collective action, a position held by the so-called philosophical radicals. These assumptions also underlying Marxist theories of social reform, in time the label "radical" was affixed to Marxists and other advocates of violent social change, thus becoming inapplicable to the gradualist reformers whom it had described previously.

In the United States, although the term is usually one of opprobrium, this was not always true in the postdepression years of the 1930s; and it is generally not true in less stable and prosperous societies. In popular U.S. usage, radicalism stands for political extremism of any variety, of the left or right; Communism serves as an example of the former, Fascism of the latter. See also

LIBERALISM; MARXISM; SOCIALISM; ANARCHISM; COMMUNISM; CONSERVATISM.

For a discussion of philosophical radicalism see Elie Halévy, *La Formation du radicalisme philosophique*, 3 vol. (1900–03; Eng. trans., *The Growth of Philosophical Radicalism*, 1928). (S. Mr.; H. M. S.)

RADICAL-SOCIALIST PARTY (PARTI RÉPUBLICAIN RADICAL ET RADICAL-SOCIALISTE; commonly called the Radicals), one of the major political parties of modern France. The party's title is misleading, because there never was anything socialist in its program, and its radicalism revealed itself only in its struggle against the Roman Catholic Church; nevertheless, in the peculiar atmosphere of French politics, this label was electorally useful. Founded in 1901 on the reunion of the Radical-Socialists with the Radicals from whom they had broken away, this party dominated the Third Republic in the 20th century as the old Radicals had done in the 19th (see FRANCE: History). The party was loosely organized and drew its funds from a small number of subscriptions, being primarily representative of sectional interests. Its power was founded on the influence of local personalities (mayors and departmental councilors), of various committees (notably those of Freemasonry), and of provincial newspapers with large circulations (e.g., *La Dépêche de Toulouse*, owned by the Sarraut brothers). Its supporters were mainly people of the urban middle class (*petit bourgeois* rather than business magnates), professional men (lawyers, doctors, and teachers), farmers, and craftsmen. It was strongest around Lyons and in the south of France, particularly in the southwest.

Radical ideology comprised (1) loyalty to the principles of the Revolution of 1789, with ready use of Jacobin slogans; (2) rationalism and anticlericalism; and (3) the systematic protection of group interests, particularly those of small tradesmen, small businesses, people with small private incomes, and the lower ranks of the civil service. Albert Thibaudet makes a distinction between the authoritarian, patriotic radicalism of such men as Clemenceau and the individualist radicalism of "the citizen against the ruling powers"—as propounded, for instance, in Alain's *Éléments d'une doctrine radicale*.

Men of the centre, between the right and the Socialists, the Radicals were essentially the governing party of the Third Republic. A Radical, Édouard Daladier, was premier at the time of the Munich Agreement (1938) and at the outbreak of World War II (1939). Immediately after that war the party seemed just a relic of a past age; and in the elections of October 1945, under a form of proportional representation, the Radicals won only 6.8% of the votes and 35 seats, whereas in 1936, under a single-member majority system of election, they had won 14.6% and 116.

During the next 15 years the party's influence rose temporarily and then fell. Its opposition to "three-party rule" by Communists, Socialists, and Christian Democrats (MRP) and, after the Communists had left the government in 1947, its holding of the balance between the parties enabled it to restore its fortunes (1945–53). The party itself was reconstituted, its newspaper propaganda revived, and public confidence in it recovered. Several coalition governments were formed under Radical leaders (René Mayer, Henri Queuille, André Marie); and in the elections of 1951 the Radicals won 72 seats. Next followed the attempt (1953–56) by Pierre Mendès-France to consolidate the party, to attract more youth into it, and to make its propaganda more cogent (e.g., in the newspaper *L'Express*), identifying it moreover with a progressive economic policy and with a liberal attitude toward the countries of the French union. Mendès-France, however, was only partially successful in the elections of January 1956 and was very adversely criticized by other Radicals, so that he had eventually to retire from leadership of the party. The parliamentary group splintered, and divisions within the party became more acute than ever before. Under the constitution of the Fifth Republic (1958) the strength of this once-powerful party was overshadowed by that of the Gaullists. See FRANCE: Administration and Social Conditions.

(J. TD.)

RADIN, PAUL (1883–1959), U.S.-Canadian anthropologist who contributed influential ethnohistorical analyses in several fields, was born April 2, 1883, in Poland and was taken to the

U.S. as an infant. He was significantly influenced during his university years by James Harvey Robinson and Franz Boas. After work at the College of the City of New York, he received the Ph.D. in anthropology at Columbia University.

Radin was primarily interested in the folklore, religion, and language of primitive peoples, contributing such works as *The Winnebago Tribe* (1915-16) and *Primitive Man as Philosopher* (1927). His view of anthropology as a branch of history and his emphasis on primary documentation are reflected in *The Road of Life and Death* (1945), *Culture of the Winnebago: as Described by Themselves* (1949), as well as in his major critical-theoretical work, *Method and Theory of Ethnology* (1933). Radin pioneered in what later became important fields of anthropology (culture-personality studies, cultural contact) and in the use of autobiographical documents; see, e.g., *The Autobiography of a Winnebago Indian* (1920), republished as *Crashing Thunder* (1926). From the 1930s on, a growing interest in Marxian sociology led him to a reinterpretation of some of his earlier formulations; see *Primitive Religion* (1937; reprinted 1964).

Though not primarily active as a teacher, Radin at various times taught at the University of California, the University of Chicago, Cambridge University, Kenyon College, Gambier, O., and Brandeis University, Waltham, Mass. For many years he was field ethnologist for the geological survey of Canada. Radin died Feb. 21, 1959. (A. M. H.)

RADIO, the radiation and detection of signals propagated through space as electromagnetic waves to convey information. Radio is one of the chief branches of telecommunication. It embraces telegraphy, telephony and television without wires, and radar.

Wireless was the original term for radio and is still widely used in Great Britain. The word radiotelegraphy was substituted generally for wireless telegraphy (and similar terms in other languages) following international conferences on radio communication held in Berlin, Ger., in 1903 and 1906.

This article, in the sections outlined below, describes the historical development of radio technology and the theories of radio wave propagation. Basic material on the nature and behaviour of radio waves may be found in **ELECTROMAGNETIC WAVES**. The growth of the industry that produces scheduled programs of entertainment, news and educational material is traced in **BROADCASTING**, while the article **TELEVISION** describes the technical aspects of that subject as well as the production of programs. Additional material on telecommunication may be found in the articles **RADIO RECEIVER**; **TELEGRAPH**; **TELEPHONE**; and **FACSIMILE TRANSMISSION**. Examples of radio aids to navigation are given in the article **NAVIGATION**. The following article is divided into these sections:

I. FORMS OF RADIO COMMUNICATION

Any form of telecommunication by radio requires a transmitter to furnish the energy for transmission; an antenna or aerial from which the energy may be propagated; the medium of propagation, which is the same as that pervading free space outside the earth's atmosphere, although its electrical transmission properties are modified by the atmosphere and the proximity and character of the earth's surface; and, finally, the receiver. In the receiver, the weak signal is resonated (tuned), amplified and demodulated (detected) to recover the original signal, which is reproduced by a teletype printer, loudspeaker or television picture tube. The highest rate of information reproduction is about 10 bits per second for high-speed code, 10,000 bits for high-fidelity sound and 10,000,000 bits for high-definition television. (A bit, or binary digit, is the binary unit of information, capable of expressing such quantities as 0, 1; yes, no; off, on, etc. See **INFORMATION THEORY**.)

These basic requirements are essentially the same for both radiotelegraphy and radiotelephony. The various forms of telecommunication are distinguished by the way that the continuous radio-frequency power generated in the transmitter (usually called the carrier wave) is interrupted or varied (that is, modulated) from moment to moment. In radiotelephony the primary controls to modulate the carrier in the transmitter are directly responsive to the human voice or to music and other sounds. In radiotelegraphy the elemental modulation is led to the transmitter in the form of a signal unit, or pulse of power, successive combinations of which, in various time patterns and usually in opposite senses (such as on-off, present-absent, plus-minus, high-low, mark-space) are given either arbitrary language code meanings or various functions in the remote interconnection of machines. In television two simultaneous (multiplexed) modulations are employed. One modulation is radiotelephonic (audio) and the other consists of signals (video) representing a range of light values of successive elemental areas into which a scene can be divided by a process called scanning. In basic radar the transmitter is pulse-modulated in a continuous manner, but without information. The informational content of radar is supplied as modulation en route at a point or points of reflection.

The modern concept of radiotelegraphy does not confine it to the system of reducing messages to Morse code signals for the purpose of transmitting and transcribing them for delivery as telegrams, or even to the system of accomplishing the same end by use of remotely actuated printing telegraph machines, important though both systems are to the world-wide radiotelegraph business. In modern usage, all information to be conveyed—words to be typed, a speech to be reproduced, a song to be sung, a switch to be operated, a card to be punched, a piece of Linotype text to be set, a television scene to be displayed or a calculating machine to be operated—can be reduced to a stream or succession of elemental units in a time domain. Radio telecommunication concerns itself with the collecting and processing of such information, if necessary its compression through codification, its propagation without wires, its detection, re-expansion or decodification and, finally, its dissemination and utilization for purposes of intelligence or control. Radiotelegraphy concerns itself with that portion of the radio telecommunication product which is a matter

of record (hence often called record communication) or control, as distinguished from radiotelephony, radio broadcasting and television, in all of which the information is only momentarily made audible or visible. Generally speaking, the pulse-transmission techniques associated with radiolocation (radar), radio navigation (loran) and radio direction-finding are considered specialized branches of radiotelegraphy.

II. EARLY HISTORY

James Clerk Maxwell was the first scientist to foresee the propagation in space of electromagnetic energy from waves originating in wires and the first to show mathematically the laws of the

FIG. 1.—HERTZ OSCILLATOR, 1887

transfer of such energy through space at the speed of light. Maxwell built upon and united the expressions of earlier mathematicians and physicists in his own equations expressing the relationship of electromagnetic forces within, and at the boundaries between, conductors and dielectrics.

In 1845 Michael Faraday was first to bridge the existing gap between light and electricity by observing the phenomenon of magnetic gyration. When he passed a beam of polarized light through transparent glass, application of a strong magnetic field was capable of rotating the axis of polarization of the light. Faraday's experiment led him to conclude, with Thomas Young, that light waves represent transverse vibrations. Later, William Thomson, Lord Kelvin, calculated the oscillatory character of electricity in a condenser discharge (1853). Kelvin passed on to Maxwell the theory that these oscillations represented successive transformations of energy between magnetic and electrostatic fields much like the kinetic-potential energy transformations in the swinging of a pendulum or in surface waves.

George Green, an English mathematician, introduced the imperfect analogy of space as an elastic medium whose dynamic properties of compression, shear and rotation—in relation to the transmission of transverse and longitudinal waves—were mathematically determinable (1828). This idea later served Maxwell for an ether model, by use of which he was able to identify light and electricity as two forms of electromagnetic wave propagation occurring at the velocity of light.

Maxwell's equations are given with their derivatives and implications and discussed at length in the articles *ELECTRICITY: Electromagnetic Waves*; *ELECTROMAGNETIC WAVES: Maxwell's Field Theory*; *LIGHT: History*. Published in 1864 and 1873, they remain a working tool of radio and telecommunication research despite the questions raised by the relativity, electron and quantum theories, the wave-corpuscular controversy and the shortcomings of the ether model.

1. Experiments by Hertz.—Radio is a superb example of a phenomenon whose principles were known to mathematicians some time before they were demonstrated practically. Maxwell made no attempt to prove physically his thesis of the identity of light and electricity, and his writings were known only by other mathematicians. Among these was H. L. F. von Helmholtz, who held the chair of physics in Berlin and whose best-known work was on the resonance of sound (1862). However, his other work in electrical oscillations and electrodynamics involved his theories in controversy with Maxwell's (1874). Among Helmholtz's pupils

was Heinrich Hertz, who in 1886–88 brought into electrical resonance, at a wave length of approximately 4 m. (or at a frequency of about 75,000,000 cycles per second [c.p.s.]), a pair of plates radiating electrical energy and a detecting loop of wire some feet away. A micrometer gap in the loop, by producing sparks that could be seen in the dark, revealed a transfer of energy as predicted by Maxwell (fig. 1).

Hertz had the benefit of the induction coil as a generator of radiation, besides laboratory types of electrical influence machines. Using these, he established that radiated electrical energy, like light, was emitted as transverse waves in all directions. Electrical waves, moreover, could be brought to a focus, reflected, refracted and polarized. Like sound, they could be set up as standing waves on wires. He also established, by measuring wave lengths and calculating frequency, that the velocity of electrical transmission through space was the same as the velocity of light, as predicted by Maxwell. He found that radio waves, because of the difference in frequencies between radio and light, would pass through certain substances opaque to light but were stopped by metallic screens. However, Hertz had no interest in using his discoveries for actual communication.

2. Hertz to Marconi.—The decade between Hertz and Marconi was marked by the development of a great deal of interest in electrical waves. The commercial successes of the wire telegraph in the first half of the 19th century, and of submarine cables and the telephone in the latter half, directed speculation toward wireless modes of operation. Experiments in conducting galvanic currents through earth and water without wires took place. Inductive devices requiring primary and secondary coils of very large dimensions were used. The principles of the first sensitive detector of faint signals—the coherer—were demonstrated, and radio signals were employed to convey intelligence for the first time.

3. The Coherer-Decoherer.—The coherence of dust particles in air when electrified was discovered by Pierre Guitard of France in 1850. In 1879 D. E. Hughes, an Anglo-American electrician, while investigating the resistance of loose contacts between carbon granules in his microphone transmitter, discovered the phenomenon on which the action of coherers depends. The coherence when electrostatically charged, and a resulting decrease in the resistance of loose brass and copper filings to the flow of a current, were noted by C. Onesti of Italy in 1884. E. Branly, a French physicist, published in 1890 his discovery that the resistance between loose iron filings in a glass tube decreases with the impact of radiated electric waves. Branly did not apply his coherer to the reception of electromagnetic waves as communication signals, but he found it necessary to tap the cohering filings mechanically to make them "decohere." Sir Oliver Lodge, an English physicist, demonstrated improvements in Branly's coherer in 1894. He used the device, in place of a Hertz loop, for the detection and pen recording of Morse signals transmitted in a laboratory by radio. Included in the ink circuit was Lodge's "trembler" or decoherer, which automatically shook the filings to restore their high resistance, thus making the device responsive to no-current as well as

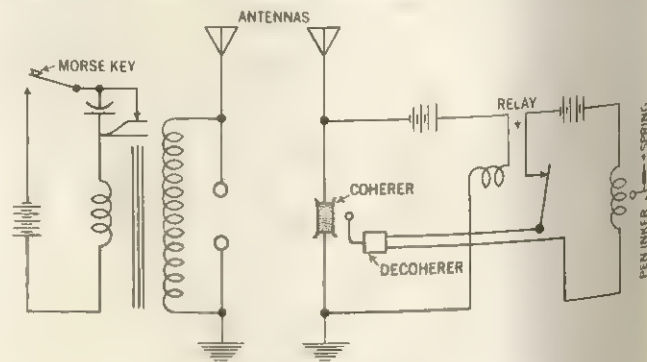

FIG. 2.—MARCONI-LODGE APPARATUS, 1895

to marking-current conditions in the dipole radio-frequency receiving circuit (see fig. 2). In 1895 A. S. Popov, a Russian physicist, in his study of distant lightning flashes, used Lodge's re-

ceiver with two improvements. One was the use of choke coils to nullify the effect of local sparking at the inker-coherer circuit relay contacts; more important was the use of an external insulated wire and a ground (earth) connection, between which the coherer was inserted. He sent Hertzian signals into his receiver over a distance of 300 yd. in 1896. Further improvements in the coherer were made by Marconi.

4. Wireless by Conduction.—Practical wire telegraphy began more or less simultaneously in Germany, England and the United States during the decade 1835-45, and quickly spread. The use of the earth as one of the two needed guides for conduction currents flowing in extended electrical circuits was discovered in 1838 by K. A. von Steinheil of Germany. It was found that two separate remote paths through earth and water could be joined in emergencies to afford telegraph communication of sorts. Samuel F. B. Morse is said to have telegraphed across the Susquehanna river in 1842 without wires or cables, by means of two pairs of plates immersed in opposite banks, one upstream and another downstream. With the coming of the microphone and a sensitive telephone receiver in the late 1870s this method found other applications, especially when the combination used was a buzzer and telephone receiver. Thus, Sir William Henry Preece, electrician to the British post office, satisfactorily communicated across the Solent (1882). In 1889 the Indian Telegraph department employed the system during floods. The buzzer telegraph became a useful military device for a few years.

5. Wireless by Induction.—Meanwhile the induction system, another method not requiring wires, appeared. Preece demonstrated in 1855, over a distance of a quarter-mile, that messages could be sent by induction, *i.e.*, using low-frequency transformer action and convection currents, instead of high-frequency displacement currents in space. In 1892 Preece signaled between two points $4\frac{1}{2}$ mi. apart. These experiments predisposed a sympathetic attitude on Preece's part toward Marconi, who came to London in 1896 to put forward his first proposals for establishing wireless telegraphy in Great Britain.

6. Early Experiments and Proposals.—The periods of these probings for wireless telegraphy bracketed the years (1886-88) of Hertz's work. The same was true for another series of experiments and ideas more directly concerned with radiation. Mahlon Loomis conceived a wireless system wherein "disturbances in the static sea" would cause electric waves to travel through the atmosphere and ground; a U.S. patent was issued on it in 1872. Thomas A. Edison reported (1875) transfers of "etheric forces" in his laboratory that caused sparks of an oscillatory nature to appear in a micrometer gap between two carbon blocks mounted in a black box with a window, but with no external connections. In 1883 George FitzGerald suggested a method of producing electromagnetic waves in space by discharge of a conductor. In 1882 and 1886 A. E. Dolbear was granted U.S. patents on "a mode of electric communication for sending signals through the ether of space," but there is no record of the apparatus having worked.

Sir William Crookes made a remarkable prophecy of wireless telegraphy in the *Fortnightly Review* (1892). He foresaw the need of better wave generators than the induction coil, of a complement of wave lengths measured in miles down to feet, of more delicate receivers, of sharper tuning and the means of concentrating power in a single direction. The article came to the attention of Marconi and profoundly stimulated him. The radio industry that Marconi founded was to be preoccupied with Crookes' telegraphy specifications for a half century. But during the latter half of that time it would be sharing attention with radiotelephony, which Crookes did not foresee and in which Marconi evinced only casual interest.

7. Guglielmo Marconi.—A native of Italy, but from 1896 identified quite as much with England, Marconi early came under the influence of Lodge's demonstrations and Crookes' prophecy of wireless telegraphy. He was the pupil of Augusto Righi, professor of physics at the University of Bologna, who was working with waves 2.5 to 20 cm. in length and had invented an early quenched-spark emitter. Unlike his predecessors, Marconi was not a laboratory scientist but an entrepreneur with a driving pur-

pose—to find the way to unguided electrical communication through space. He dedicated his life to translating radio from the laboratory to the marketplace, always looking for the slightest advance in reliability of wireless equipment and in the distances over which it would work. Marconi saw the commercial usefulness of a method of electrical transmission that, because it was not restricted by wires or cables, could reach an unlimited number of receivers anywhere at the same time.

Marconi was first to transmit and receive signals by Hertzian waves purposefully directed but without wires (1895). He used an induction coil with a telegraph key in the primary circuit. Across the secondary circuit was an untuned spark gap. Marconi did not terminate the gap in a dipole, as had Hertz and Lodge, but in a ground plate for one pole and in an elevated metal cylinder for the other. For a receiver he used a simple coherer with improvements in sensitivity. By the end of the year he had increased the transmitting range to more than a mile.

In 1896 Marconi went to London, secured patents on his system and interested government officials in it. Ranges of 2 to 9 mi. obtained that year were gradually increased to 200 mi. by 1901.

III. MARITIME WIRELESS AND THE VACUUM TUBE

Marconi set the pace for widening the transmission range of wireless. In 1897 he established the station at Needles, on the Isle of Wight, that took part in several records in wireless: 1897—first maritime use of wireless in England, to a tugboat 18 mi. away; 1898—first paid-for wireless telegram; 1899—first newspaper published aboard ship using press matter sent by wireless, 56 mi.; 1901—first 200-mi. communication. Marconi also was the first to bridge the English channel by wireless, in 1899.

1. Maritime Wireless.—The fact that radiated waves carried well over water led to the entrance of commercial wireless into the maritime field, where it filled a need not served at all by wire telegraphs. Apart from its obvious usefulness to ship owners in communicating with ship captains and pursers during the course of a voyage, it was quickly put to use by the press, by the military and in sea rescues.

By 1904 the role of wireless in summoning help to ships was so important that adoption of a universal code call of distress was in order. Addition of the letter D (for danger) to the "all stations" collective call CQ gave the CQD signal, eventually replaced by the Morse mnemonic SOS. When radiotelephones became common, especially on aircraft, the voice of distress, "May Day" (from the French *m'aidez*, "help me") was added.

2. Spread of Commercial Wireless Telegraphy.—Marconi's influence rapidly spread to other countries. A. K. H. Slaby saw Marconi's apparatus in England and introduced it into Germany in 1897, and the first German commercial wireless station was established on Borkum Island in 1900. Pioneer wireless work in Germany was also done by K. F. Braun, G. W. A. von Arco, Alexander Meissner and the firm of Siemens and Halske. Out of an amalgamation of these interests the Telefunken company was created in 1903.

Two outstanding names appear in the early wireless annals of the U.S.—those of R. A. Fessenden, physicist, and Lee De Forest. Fessenden lectured on Hertzian waves and experimented with them prior to 1900, when he was engaged by the U.S. weather bureau to develop wireless as a weather forecasting aid. He became a prolific producer of wireless inventions. De Forest, while a student in 1898, was attracted by demonstrations of the Hertz experiments. As Marconi had been, De Forest was influenced by the predictions of Crookes regarding the future of wireless. He set out to produce a better detector of waves than the coherer, and he produced several inventions of great importance.

3. Transoceanic Operation.—In 1900 Marconi built a station at Poldhu, Cornwall, Eng., that established a number of records, and in 1907 he built another station in Clifden, County Connemara, Ire. The Federal Telegraph company opened a radiotelegraph service between San Francisco, Calif., and Honolulu, Hawaii, in 1912. The American Marconi company opened a similar circuit in 1914 and extended service across the Pacific to

Japan by manual relaying in Hawaii during the next year.

4. Improvements in Transmitters.—The improvements in transmitter equipment and antennas in the first quarter of the century greatly extended the range and reliability of long-wave and medium-wave radiotelegraphy. Until the introduction of the vacuum tube, spark gaps, arcs and alternators took many forms during the 20-year period beginning around 1903.

Rotary Spark Gap.—Invented by Fessenden, the rotary spark gap consisted of a toothed or spiked wheel turning between two electrodes. A whistle-like note could be produced to any desired audible pitch by proper selection of wheel speed and number of teeth. Self-cooling, the gap could be decreased to any minimum length desired. The rotary spark gap was widely used in the 1906–20 period.

Quenched Sparks.—As the power supplied to ordinary open spark gaps and their associated oscillatory circuits was increased over the years, it was found that the sparking rate could be increased if ionization of the gas between the electrodes could be prevented. A technique was discovered by the German physicist, Max Wien, in 1906, wherein sparks—which in that day were thin and often several inches in length—were increased in volume but reduced to a fraction of a millimetre in length. This resulted in an abrupt decay (or quenching) of the oscillation produced by the spark. The frequency emitted was therefore that of the circuit coupled with the antenna, excited by rapid, successive impacts from the quenched gap. Arc-over was prevented by using large electrode areas cooled by circulating air or water. For very rapid sparking rates a high-voltage direct current could be used, with an oscillating circuit in series with the quenched gap. As installed by the German Telefunken organization for telegraph use in 1909–15, the quenched gap was fed from alternators producing 500 to 1,000 c.p.s.

Rotary gaps and quenched gaps made the emitted telegraph signals more distinctive and more easily identifiable by the receiving operator, who often had to read them through the interference of static and other transmitter signals. Rotary and quenched gaps produced tones more or less unique to each station. Despite such advances, it was clear that the intervals of no power, between bursts of rapidly decaying ether disturbances caused by discrete sparks, could not be reduced so long as sparks were employed; some source of continuous-wave production had to be found.

Marconi Timed Spark.—Marconi's timed-spark system made it possible to approach continuous-wave generation. It used stagger-toothed wheels rotating on a common axis. These wheels drew off sparks at a faster rate than the single spider used by Fessenden and others. By careful design the wheels could be timed so that the decaying oscillations produced by one set of teeth and its associated spark gap were overlapped in phase by oscillations developed by a second set, and so on. The system was adapted only to very long waves (very low radio frequencies), it required bulky equipment to maintain the necessary stability, it had to be designed so that the frequencies produced matched the natural frequency of the antenna and its operation involved many other critical factors.

Arc Oscillators.—W. B. Duddell, an English engineer, discovered in 1900 that an arc lamp could be made to "sing" a musical note if it was placed in a direct-current circuit containing an inductance and a capacitance. V. Poulsen of Denmark, by cooling the lamp electrodes and enclosing the arc in an atmosphere of

emitted the first pure continuous waves in the low-frequency wireless field. However, Poulsen's arc was not tested successfully until 1908, when it worked over a distance of 150 mi. Meanwhile, in 1906, the German Telefunken arc appeared; by 1913 Telefun-

FIG. 4.—LOOSE COUPLING AND FLEMING VALVE, ABOUT 1907

ken's Nauen station used it over a range of 1,550 mi. In 1910 the Federal Telegraph company brought the Poulsen arc to the United States. It was installed as standard equipment by the U.S. navy in 1912 and continued in use through World War I.

High-Frequency Alternator.—Fessenden applied in 1901 for a U.S. patent on a high-frequency alternator for the generation of continuous waves that would make possible the transmission of the human voice by wireless telephony. To Fessenden's specifications, E. F. W. Alexanderson, a pupil of Slaby working in the U.S., built in 1903 a 10,000-c.p.s. alternator. Later he built one of 80,000 cycles, with which, at Brant Rock, Mass., Fessenden was the first to broadcast music and speech (1906). Alexanderson's problem was the design of multipolar machines (e.g., 300 poles mounted on the stator) with rotor speeds of about 20,000 r.p.m. and air-gap clearances of about 0.015 in. Such a machine, developing 100,000 c.p.s., was built by Alexanderson in 1909 for radiotelegraph use.

Resonance and Tuning.—Lodge patented in England, in 1898, the use of adjustable inductance in the transmitter, antenna and receiving circuits of wireless systems. Lodge called this syntonizing tuning (see fig. 3). While the patent was in conflict with some of Marconi's claims, Lodge had an influence on early tuning theory and the adaptation of antenna sizes and configurations to the frequencies being emitted and detected. John S. Stone applied for four-circuit tuning patents in 1900 and was the first in the U.S. to assert that antenna circuits and spark and detector circuits could be independently tuned and loosely coupled together, thus increasing selectivity (see fig. 4). Stone also studied the tuning of telephone wires and their adaptation to the guidance of electromagnetic waves.

In wireless, as in wire telephony, a parallel attack on the problems of resonance had been made.

Antennas.—Antennas were found to have a natural resonance period important to the tuning of a circuit consisting of antenna, ground and coupling inductance. Marconi and his organization, Lodge, Fessenden and many others developed formulas for antennas of various virtual heights, for optimum ratios of antenna lengths to wave lengths and for various configurations—notably the vertical antenna and the flat-top antenna supported between towers and between ships' masts. Alexanderson invented the multiple-tuned panel transmitting antenna. It divided a directionally pointed, horizontal, tower-supported antenna into sections connected through down leads and tuning inductances to ground at various points throughout its length of approximately 900 ft. Alexanderson and his assistant, Harold Henry Beverage, developed a "barrage receiver" that incorporated directional discrimination and required long horizontal antennas (1916). In 1921 Beverage patented the "wave antenna" that became standard for long-wave reception throughout the world. It consisted of a wire supported on a straight-pole line of the length of one wave (approximately nine miles in practice) and oriented to the direction of arrival of the wave. It had the useful property of rejecting static that came from any other direction.

5. Improvements in Receivers.—The counterpart of increased power in transmitters was increased sensitivity in receivers.

FIG. 3.—TUNED CIRCUITS AND CRYSTAL DETECTOR, ABOUT 1903

hydrogen, raised Duddell's limit of 10 kc. per second to 100 kc. per second; and, when coupled to an antenna, the arc generated and

The single step of most significance was the substitution of a pair of head telephone receivers or headphones for the early pen inker as the receiving device used by the operator. Headphones were sensitive enough to work directly in a rectifying receiving circuit when a series potentiometer and a shunt-blocking condenser were added (see fig. 3). Between about 1903 and 1916 the standard method of telegraphing by wireless was headphone reception of hand-keyed Morse code (ship-to-shore) or slow-speed automatic Wheatstone (transoceanic) transmission.

As in the case of spark gaps in transmitters, many improvements were made in the rectifier element (detector) of receivers. These improvements served a vital purpose in the interval 1902-20, before the De Forest three-element vacuum-tube circuit became available for general use after World War I. In Marconi service the coherer was replaced by the magnetic detector. As developed by Marconi in 1902, it was capable of moving a relay so that the relay could produce recordings of signals on paper tape. By 1907 the coherer had been generally outmoded by magnetic, electrolytic and crystal detectors in circuits of the kind shown in fig. 3.

Before 1900, Hughes in England had found that a steel needle resting lightly on a carbon block would rectify radio-frequency waves in a manner similar to a coherer but without requiring a decoherer. With headphones, the steel needle became the earliest form of crude wireless rectifier, but its use was short-lived. Contemporary with the magnetic detector was the electrolytic detector, an invention of Fessenden in 1902, consisting of platinum wire dipped in nitric acid. Beginning in 1903 G. W. Pickard, an American engineer, began experimenting with the rectifying properties of magnetite and other crystals that had surface spots sensitive to radio signals upon contact with wire probes called "cat whiskers."

In 1906 Pickard discovered a superior crystal in silicon, and in that same year Gen. H. C. Dunwoody of the U.S. army discovered that carborundum and carbon in contact were less sensitive to vibration than other combinations and therefore were adaptable to shipboard use. Pickard used a combination of zinc oxide and chalcopyrite in contact; also tried were galena, molybdenum and other crystals. The independently conducted, trial-and-error search for these materials was in marked contrast to the organized scientific research in 1948, involving point contacts on germanium, that resulted in development of the transistor. Crystal rectifiers were the mainstay of wireless until they were gradually replaced by electron tubes.

6. The Electron Tube.—Sir John Fleming's vacuum diode valve of 1904, based upon his discovery that the "Edison effect" could be applied in a wireless receiver circuit for the detection of incoming waves, was a rectifier. It fulfilled the function of a crystal as a detector of high frequencies (see fig. 4). It was the first of a long series of electron tubes that had a heated source of a stream of electrons (cathode) and a collector plate, both in a partially exhausted glass housing with external electrical connections. The development of the electron tube is traced in the article *ELECTRON TUBE: History*. The De Forest triode audion of 1907 was the most important of the electron tube series. It contained two features absent in Fleming's valve: an external local battery, connected between plate and cathode, from which the tube derived its power to amplify weak input signals; and a third electrode, the grid, interposed in the electron stream and capable of controlling the plate current in accordance with incoming radio-frequency signals. Under optimum conditions, De Forest's triode displayed high amplification characteristics as a detector, although Fleming's valve had not. However, it was not until 1912 that the triode's amplification was stabilized and its versatility became clear. In that year H. D. Arnold and Irving Langmuir independently found that the triode amplifier could be stabilized if pumped to high vacuum, and De Forest increased amplification by operating his tubes in cascade—the plate output of one tube fed into the grid input of a second tube, etc. De Forest discovered that the audion could be made to oscillate, in suitable circuits, so as to generate radio frequencies. This meant that the vacuum tube could be used for transmission as well as reception. E. H. Armstrong in 1913 and De Forest in 1914 filed conflicting patent

applications on the feedback circuit (see *RADIO RECEIVER: History*). The feedback circuit led a portion of the amplified plate current back into the grid of the same tube, greatly increasing its sensitivity by regenerating weak signals.

7. Developments During World War I.—Maritime wireless telegraphy was generally in use on ships and between ships and shore stations by the outbreak of the war. Arc transmitters up to 500 kw. in capacity had been installed at naval stations in the United States, and the Marconi timed-spark system linked units of the British commonwealth. New German Telefunken stations erected in the U.S. were among those that warned German ships, upon the declaration of war, to make for neutral ports. The British fleet was recalled by radio. During this period very long-wave transoceanic radiotelegraphy became well established for military purposes, using arcs and alternators for transmitting and triode tubes for receiving. In 1918 the U.S. army erected its Lafayette station at Crois d'Hins near Bordeaux, France, for transatlantic communication. It achieved world ranges on a wave length of 20,000 m. The original plant comprised two Poulsen-Federal arcs rated at 1,000 kw.

The Heterodyne Principle.—Radio frequencies generated by arc and alternator were above the range of audibility in a telephone receiver, so that they had to be modulated at a steady audible tone before being turned on and off with a telegraph key. This modulation was accomplished at either the transmitter or receiver. The German inventors modulated their alternators by means of a tone wheel. Poulsen tone-modulated his arc with an interrupter. Fessenden invented a method of tone-modulating a circuit at the receiver instead of at the transmitter by generating at the receiving station another high frequency that differed from the transmitter frequency by a value within the audible range. The device that produced this steady interference pattern was called a heterodyne apparatus (1902). Fessenden used the heterodyne principle at his Brant Rock station in 1904, and it was necessary to generate the beat frequency by a ponderous local arc. Nevertheless, U.S. navy experiments in 1913 demonstrated the superiority of this method for radiotelegraphy. With the introduction of the vacuum tube as an oscillator in 1912, a simple receiving circuit component became available to generate a heterodyne beat-note audible in headphones. To solve a military problem with the U.S. army signal corps in Europe in 1918, Maj. E. H. Armstrong converted a received radio-frequency signal into an intermediate, supra-audio frequency by beating it with the output of a local oscillator, detecting signals twice before giving them audio amplification. He called this the superheterodyne method and patented it in 1919-20. It possessed advantages of stability over other methods of amplifying signals above the audio range. With the advent of the screen-grid tetrode in 1927, the superheterodyne became the most widely used receiver circuit.

Radio Direction-finding.—Direction-finding, or radiolocation, began in wireless telegraphy as a specialty of wave-direction measurement. In modern aviation and in some marine work direction-finding is an auxiliary function of radiotelephony. The original work on direction-finding was performed by Stone in 1904 and by E. Bellini and A. Tosi in 1906. The patents of the Bellini-Tosi system were acquired by Marconi in 1912, and in that year the first English merchant vessel was equipped with a direction-finder. Credit for major improvements thereafter is shared by an American, F. A. Kolster (1913); Marconi's assistant, Capt. H. J. Round, whose devices tracked down the German fleet in the battle of Jutland (1916); and R. L. Smith-Rose, a British physicist. Because of its usefulness in World War I, direction-finding equipment did not find full commercial use until the period 1921-25, by which time it employed vacuum-tube circuits. By 1925 the radio compass had come into widespread shipboard use.

8. Radiotelephony.—The technique of radiotelephony represents the combination of two developments: high-powered radiotelegraphy and weak-current wire telephony. From the time of Alexander Graham Bell and Hertz until 1906, the two modes of communication had been separated in orders of magnitude of power and frequency, even though they derived from a common theoretical source in Maxwell's equations. As early as 1896, Stone and

M. I. Pupin were involved in a patent controversy in applying telephony to Hertzian waves.

The Microphone.—The first type of transmitter for voice pickup was the telephone instrument patented in 1876 by Bell. He originally used the same type of coil-diaphragm instrument for talking and listening. Bell, and also Elisha Gray, used transmitters in which the voice sound varied the electrical resistance and thus caused variations in the currents in telephone circuits. In 1877 Émile Berliner and Edison discovered that sound pressures on a diaphragm could be made to produce variable electrical currents. Edison invented the carbon-granule telephone transmitter in 1886. The term microphone, coined by Sir Charles Wheatstone in 1827 to describe an acoustical amplifier, was first used in connection with telephony by Hughes in 1878. In that year Hughes devised a sensitive microphone transmitter in which the variable circuit resistance consisted of a carbon rod resting in grooves in two carbon blocks. Improvements in detail upon the Edison and Hughes transmitters led to the development of modern microphones. Subsequent refinements that resulted in the high-quality microphones used in radio, television and recording studios are traced in the article MICROPHONE.

Modulation by Microphone.—The direct-current singing arc was made to "speak" audibly and its light to vary when a microphone was coupled to its circuit by a transformer. Such a "photophone" was built by H. Hays and Bell in 1897. It was not devised to generate radio frequencies but to transmit audio frequencies over a light beam. A number of attempts were made to introduce a microphone at various points in spark-energized wireless circuits without success, although Fessenden is generally credited with having been first to transmit speech over a distance of a mile, using a high-speed, interrupted-spark transmitter (1900). A. F. Collins used a microphone in the primary of an induction coil, with antenna and ground but without spark balls, to transmit over a distance of three miles in 1902. Spark telegraph signals, especially on low radio frequencies, were too powerful and too widely spaced in time to be modulated, even by water-cooled microphones.

Use of Arcs and Alternators.—Poulsen used his hydrogen-arc generator of continuous wireless telegraph waves in 1904 to transmit voice over short distances. In Germany H. T. Simon and M. Reich (1903) and O. Nussbaumer (1904) suggested the application of high-frequency alternating currents to the purposes of wireless telephony. In 1906 the Telefunken arc of Von Arco was voice-modulated, making it possible to talk by wireless over a span of 25 mi., and in the same year Fessenden staged the first demonstration of the broadcasting of music and voice by radio, using a water-cooled microphone and an Alexanderson 80,000-cycle alternator at Brant Rock. Reception was reported by radio operators aboard many ships at sea. De Forest demonstrated an arc radiotelephone in 1907 in tests between a ferryboat on the Hudson river and its terminals in New York and New Jersey. Using a liquid microphone to modulate an arc, F. Majorana in 1908 telephoned from Rome, Italy, to Sicily, a distance of 300 mi., and in 1910 H. P. Dwyer used a Poulsen arc to telephone from San Francisco to Los Angeles, Calif. (490 mi.). In 1911 Alexanderson built a high-frequency alternator with a laminated-iron field, designed to act as a self-contained magnetic amplifier. Its input was a microphone and its output a varying field flux that amplitude-modulated the generated continuous waves. In 1914 Marconi long-wave radiotelephone signals originating at Clifden, Ire., were received aboard two Italian war vessels off the coast of Sicily, 1,750 mi. away.

IV. THE RISE OF BROADCASTING

Medium-frequency telephone broadcasting and short-wave telecommunication dominated the decade 1920-30. The radiotelephone, useful for private conversations, became most valuable in public mass communication and entertainment. Public demand for broadcasting service and equipment caused manufacturers to demand new electronic devices, circuits and equipment. Broadcasting studios, feeder networks and overseas remote pickups became commonplace. Early radio by-products, including public-address systems and telephotography, presaged the decade of elec-

tronics that was to follow. Short-wave transmission also came into its own during the 1920s.

1. Improvements in Transmitters.—Better performance in transmitters stemmed in part from transmitting tubes of larger size and greater efficiency. Two important improvements were the copper-to-glass seal and the water-cooled tube (1922). Broadcasting transmitters, which in 1922 operated at outputs of less than 500 w., were increased in power; 50-kw. stations were common in 1928, and by the early 1960s outputs had reached 500 kw. Efficient use of power by the transmitter was found to be economically important, and efficiencies were increased by such advances as the constant-current system of modulation of R. A. Heising (1921), the class C amplifier (1932) and W. H. Doherty's linear radio-frequency power amplifier (1936).

Jacques and Pierre Curie discovered the piezoelectric effect in 1880, and they later found that if a high-frequency field is applied to a crystal held under pressure, and if the applied frequency exactly coincides with the natural period of vibration of the crystal, the crystal will oscillate and produce useful alternating voltages between its surfaces. This property proved invaluable in preventing radio transmitters from wandering off assigned frequencies. G. W. Pierce found that the resonance of a crystal is very sharp. He was issued several patents on applications (1924 to 1931) for vacuum-tube circuits containing quartz crystals as oscillating-circuit stabilizers. The first use of crystal-controlled master oscillators took place in 1923.

There are other less precise but effective ways of accomplishing frequency control. Pierce investigated magnetostriction effects in nickel, while W. H. Eccles, of the Marconi staff, used tuning forks as early as 1901 to keep stations on frequency. Identically ground crystals were employed on a wide scale during World War II in transmitters and receivers, and the practical subdivision of the radio-frequency spectrum among thousands of users in the middle of the 20th century was made possible only by crystal frequency controls.

2. Amateur Radio.—Young men had turned to wireless telegraphy as a hobby in the period 1903-12 in the same spirit that their fathers had strung rooftop wire telegraphs between houses. Thousands of the long-wave transmitters shown in fig. 3 and 4 (but without receiving tubes) were installed. Unfortunately amateurs increasingly interfered with commercial and government wireless, and in 1911-12 they became subject to licence restrictions. During World War I amateur sets were sealed; however, the operators' talents proved so valuable in military service that they were encouraged to resume amateur operations after the war. Amateurs adopted vacuum tubes when these became available around 1919, and they became an important source of listening material for the many thousands of people who bought broadcast receivers in the years following 1920.

In resuming operations in 1919, the amateurs had been crowded into a medium-frequency band that was not broad enough to accommodate them. They had also been assigned a medium-high-frequency portion of the spectrum believed unsuitable for long-distance operation. The good use to which they put these bands in 1920-21 was their most valuable contribution to the development of radio. In 1921 a U.S. amateur, P. F. Godley, with the co-operation of British amateurs and the post office, set up a receiver in Ardrossan, Scot., through which he received from a group of six American amateurs at Greenwich, Conn., a 12-word message in radiotelegraphic signals. The distance was 3,200 mi., the power 1 kw. and the wave length 230 m. (1,300 kc.). Soon American, British, French and other European amateurs by the hundreds were in frequent communication at low power in this band as well as on 180 m. In 1923 amateurs used low-power, 100-m. waves to talk between New York and California.

3. Commercial Short-Wave Radio.—Commercial interests were caught off guard by the amateurs' successful exploitation of the upper medium-frequency (MF) and the lower high-frequency (HF) bands. Marconi had never lost faith in the possibilities of short waves, but he had dropped the investigation of them in the 1890s in favour of long waves that were yielding him quicker results. He had taken out a patent on "beamed transmission" in

1905, and in 1916 assigned C. S. Franklin to investigate short waves. Franklin's results, published in 1922, indicated that short waves, 15 to 100 m. in length, were suitable only for distances less than 200 mi. This conclusion was controverted by the experience of the amateurs, whose records spurred more experimentation by Marconi, the Radio Corporation of America and the American Telephone and Telegraph company. The first commercial long-distance radiotelegram dispatch by short waves was sent from Belfast, Me., to Buenos Aires, Arg., in 1923. In the same year Marconi dispatched his yacht "Elletra" to test 100-m. short waves at sea as received from Poldhu, using reflectors designed by Franklin to concentrate the transmitted energy in a beam. The signals from Poldhu were heard 1,200 nautical miles in the daytime and double that distance at night. In 1926 beam transmission was considered practical for commercial use, and by 1928 Marconi stations had been erected in England, Canada, Australia, South Africa and elsewhere throughout the British empire. The Radio Corporation of America had abandoned its ambitious plans for a long-wave radio central station and was installing short-wave equipment. By 1930 the American Telephone and Telegraph company had made an almost complete transition to short wave.

Opening up of the extensive short-wave portion of the radio spectrum made room for thousands of long-distance and other services that could not have been accommodated on longer waves. Antennas became smaller and less expensive to build, had increased radiation efficiency and had substantial portions of their energy directed toward desired reception points. Directivity of antennas reduced the interference between stations and permitted worldwide sharing of channels. Interference by static caused by distant thunderstorms was less. Because of these advances, transmitter power could be reduced or the existing power could be used to make transmissions more reliable. Short-wave radio was adapted to long-distance telephony and to high-speed, multichannel telegraph operations. After 1927 virtually no new long-wave radio circuits were established, and most of those in use at that time were gradually abandoned. The long-wave spectrum is still useful, to a limited extent, for specialized military radiotelegraph services and for navigation.

The Kennelly-Heaviside Layers.—In 1902, long before short waves were being used, A. E. Kennelly of Harvard university and the British mathematician Sir Oliver Heaviside independently reasoned that a stratified layer must exist in the upper atmosphere; between that layer and the surface of the earth the long waves of wireless must be contained, and this fact accounts for the waves not leaving the earth tangentially at the horizon as light waves do. With the beginning of short-wave investigations, this theory was rapidly expanded. A. H. Taylor accounted for the ground- and sky-wave components of short waves; L. W. Austin reasoned that sky waves underwent refraction rather than reflection; and Ernest Rutherford attributed refraction to the presence of free electrons in the layer. Frank Conrad developed the "multihop" theory of repeated refractions in the layer and reflections from the earth's surface. The height of the layer was measured by Sir Edward Victor Appleton in England, by triangulation, and by George Breit and Merle A. Tuve in America, who measured the echo of a transmitted pulse. The latter method eventually revealed the existence of several concentric layers rather than one. (See *IONOSPHERE*.)

Diversity Reception.—H. H. Beverage and H. O. Peterson, observing transoceanic short-wave signals in 1925, found that fading does not occur simultaneously in two receivers working on antennas spaced a short distance apart. This led to the development of space-diversity reception, in which the combined (or overriding) signals from two or more receivers, working off carefully placed, separate antennas, govern the operation of a receiving relay, which automatically selects the strongest available signal.

V. SPECTRUM EXPANSION AND ELECTRONICS

Continued progress in broadcasting, and a new probing of the ionosphere by short waves, tied the decade 1930-40 to its predecessor. In the period between 1933 and 1937, improved designs for broadcast antennas made possible higher efficiencies and better control of directional effects, thus further reducing interference be-

tween stations. Continuing research in the high-frequency portion of the spectrum led inevitably to exploitation of the short-wave band for international broadcasting. By 1932 broadcast transmitters were operating with sidebands 8,000 c.p.s. in width, making it possible to transmit undistorted voice and music tones as high in pitch as 8,000 c.p.s.; this meant better fidelity in reproduction (FM broadcasting almost doubled this tonal range two decades later), but unfortunately the quality of the receivers then in use was not equal to that of the transmitters.

1. Electronics.—A widespread movement to apply radio theory and apparatus to other fields began in the middle 1930s. The radio industry contributed the electron tube, the photoelectric cell, the oscilloscope, electronic amplifiers, the principle of feedback for automatic control and techniques for utilizing both audio and radio frequencies in many ways. The term electronics came into use in the mid-1920s to designate all of the theoretical and applied work involving the movement of electrons in a vacuum. About 1928 electronics began to be used as a collective term for all the applications of the electron tube and its associated circuitry to purposes not directly associated with radio emissions.

2. Marine Radiotelephony.—The earliest demonstration of two-way marine telephony was aboard the U.S.S. "New Hampshire" in 1915. In World War I the long-wave radiotelephone was used to communicate with submarine chasers and other small vessels and aircraft. Ship-to-shore radiotelephony was tested in 1920 on low-power long waves, and commercial radiotelephone service between land and steamships began in 1929 with the installation of radiotelephone equipment on the "Leviathan." By 1933 long-distance, short-wave, ship-to-shore radiotelephony was commonplace on the North Atlantic. Extensive use was made after 1934 of short-wave radio in commercial telephone service to small craft in coastal waters, as well as to private aircraft.

3. Commercial Radiotelephony.—The first commercial long-wave radiotelephone circuit was established in 1920 between Long Beach, Calif., and Catalina Island, a distance of 30 mi. One-way transatlantic tests on long waves occurred in 1923, and commercial transoceanic radiotelephone communication began in 1926, using long waves; short-wave transoceanic radiotelephony came in 1929. The multiple-unit, steerable receiving antenna was first used in 1934. Independent double-sideband transmission on a common carrier frequency originated on the Netherlands-Java short-wave circuit in 1937, and by that year the principal countries of the world were interconnected by 92 groups of radiotelephone circuits, making it possible to talk between any of about 93% of the world's telephones.

4. Aviation Radio.—Radio serves aircraft not only as a means of communication but as a navigational aid. The problems of designing aviation radio equipment are similar to those encountered in marine equipment, but they are aggravated by restricted space for equipment and antennas, as well as by interference from other electrical equipment, by unusual types of static and by a varying power supply. Also, in order to maintain continuous communication and navigation facilities, it is necessary to work several channels independently and simultaneously, and two or more transmitters and receivers therefore are required.

In the United States, the first navigational aids to aviation appeared in 1920, when the post office department established ground stations for the airmail service. By 1930 a radio-range beacon system had been developed for universal application to airways, and in 1931 a radio beacon system had been devised for the "blind" landing of aircraft, although it was not officially adopted until later. In Europe and the United States very short waves (above 30 mc.) were being used in instrument-landing systems in 1935. A rotating radio compass, making possible automatic direction-finding for airplanes, was developed in 1936. It worked as a homing device in connection with radio beacons. Radio altimeters, working on the principles of the marine depth-finder, became available in 1938. The first U.S. blind-landing system, in which a definite radio slope of descent could be followed by a pilot, was installed at Indianapolis, Ind., in 1940. (See *AIRCRAFT INSTRUMENTS*.)

5. Mobile Radio.—The Detroit, Mich., police department in

1928 became the first to dispatch police squads by radio, and by 1935 about 400 cities in the U.S. had police radio service, some in the 30- to 40-mc. bands. Widespread two-way operation from police cars and private vehicles came with the opening of the ultra-high-frequency (UHF) spectrum after World War II.

Broadcast receivers for automobiles were introduced in 1932, and within a year they were in wide use.

6. Advances in Techniques.—The principles of negative feedback, set forth by Stuart Ballantine in 1923, were spectacularly applied by H. S. Black in 1934 to produce wide-band, noise-free amplifiers having marked stability of operation. These amplifiers also were capable of a high degree of linearity (the ability to produce an amplified output signal with a wave form as similar as possible to that of the input signal over a wide range of frequencies); thus they could reproduce a much wider range of modulations without distortion.

In 1930 a widely published graph of the radio spectrum showed all waves shorter than 10 m. (30 mc.) as "not now useful." Yet there was general agreement that radio would have to expand into the higher frequency bands. Marconi's 1896 patent had contemplated using waves having a minimum length of about 25 cm. (10 in.); i.e., a maximum frequency of about 1,200 mc. When tubes capable of generating such ultra-high frequencies did become available, no time was lost. Report was made of experiments with 3-m. VHF waves in 1930, and in the period 1930-35 there were many more reports, covering UHF as well as VHF. The first important microwave telephone circuit was established across the English channel (Dover-Calais) in 1931, using an 18-cm. wave (UHF). The first multichannel telephone microwave circuit joined Belfast, Ire., with Stranraer, Scot., in 1937, on 3 to 6 m. (VHF). Transmission of super-high-frequency (SHF) electromagnetic waves in hollow wave guides was reported by W. L. Barrow in 1936 and by G. C. Southworth in 1937.

VI. PULSE TECHNIQUES AND TELEVISION

During World War II radio development was cloaked in military secrecy, but the easing of restrictions in 1946 disclosed as many accomplishments as in any previous decade. The most important advance had been radar, not alone because of its military successes but because radar theory and the electronic apparatus and techniques that arose from it were basic to the further utilization of the highest-frequency reaches of the radio spectrum. Out of military research, too, came such new concepts as printed circuits, modular construction and miniaturization. The end of the war also permitted resumption of work on television, which rapidly began to overtake radio as the most important entertainment medium in many countries.

1. Modulation.—The continuous wave of power (the carrier) delivered into an antenna by an oscillating electron tube may be varied or modulated, in its strength or amplitude, by voice signals from a microphone. The process is called amplitude modulation (AM). As an extreme example, amplitude may be varied suddenly between zero and full strength by working a telegraph key, thus either interrupting a steady musical tone that modulates the carrier or interrupting the carrier itself; wireless began by using such coded interruptions of a train of sparks. The process of amplitude modulation, as used in standard radio broadcasting, consists in varying the amplitude of the carrier wave at a rate identical to the frequency of the sound to be transmitted; e.g., if a tone with a frequency of 1,000 c.p.s. is to be broadcast, the strength of the transmitter carrier is varied 1,000 times per second. Frequency modulation, as its name suggests, consists in varying the frequency of the transmitter carrier wave (while its strength remains constant) at a rate identical to the frequency of the sound to be transmitted. The outstanding advantage of FM is its freedom from interference by atmospheric and man-made electrical noises. These unwanted noises are of an amplitude-modulated nature and hence are not detected by circuits in FM receivers.

It also is possible to transmit signals by other types of modulation, some of which are important to radiotelephony, radiotelegraphy, picture transmission, television and radar. In FM telegraphy, for example, two tones, differing in pitch, convey the dots

and dashes of the code signals; this was done with Poulsen arcs in the period 1912-22. Alternatively, the carrier itself may be varied in frequency by changing certain circuit constants; this is called frequency-shift keying and was developed during World War II. FM was applied generally to telegraph carrier transmission over wires in the U.S. during and after 1937. In 1945 it was applied to microwave radio for public telegraph service. Frequency modulation also is used to transmit the sound for television.

Pulse Modulation.—An electron tube can be overloaded drastically but safely if the overloads are of extremely short duration and are interspersed with relatively long periods of inactivity. One electron tube especially designed for this type of service is the magnetron, a two-plate version of which was described by A. W. Hull in 1921. A water-cooled magnetron was available in 1930 having an output of 5 kw. at 20 mc. and 1 kw. at 85 mc. (in the HF and VHF frequency ranges). However, successful ultra-high-frequency radar had to await development of the British 10-kw. multicavity magnetron tube (1940), public announcement of which was withheld, for security reasons, until 1946.

The signals sent by radar and other pulse methods may be likened to a line of poles along a roadway. So long as the poles are equally spaced and of equal height they convey no information. It is possible, however, to convey information in any of three ways: (1) by varying the height of the poles (pulse-amplitude modulation—PAM); (2) by moving individual poles a short distance one way or the other from their normal, equally spaced positions (called both pulse-position and pulse-time modulation—PPM or PTM—developed in 1944); or (3) having grouped the poles into sets of five, for example, by omitting certain poles in accordance with a prearranged code (pulse-code modulation—PCM—developed in 1947). Pulse-modulation methods were adapted to multichannel telegraphy and eight-channel telephony, and pulsing was found particularly adaptable to microwave relay transmission in the super-high frequencies. Because of steepness of the wave fronts of the pulses and because the signals could be completely regenerated (i.e., rejuvenated) at each repeater point, they were singularly free of noise, approaching the reliability and continuity of a wire line.

Single-Sideband Techniques.—Single-sideband (SSB) operation had been applied to long waves in 1927-37, but its potentialities for full utilization of the radio spectrum did not begin to be realized until the late 1940s. Before the advent of SSB, it was necessary to transmit both the upper and lower sidebands of speech, each of which is the mirror image of the other (fig. 5[B]);

FIG. 5.—PRINCIPLES OF SINGLE-SIDE-BAND OPERATION (A) WAVE FORM OF UNMODULATED CARRIER; (B) CARRIER MODULATED NORMALLY WITH UPPER AND LOWER SIDEBANDS, ONE REDUNDANT; (C) DIFFERENT SIGNAL, DOUBLE SIDEBANDS AS IN (B); (D) SIGNALS OF (B) AND (C) IN SINGLE SIDEBANDS, REDUNDANCIES SUPPRESSED, WITH NO INCREASE IN NORMAL TOTAL BANDWIDTH.

one sideband is the sum of, the other is the difference between, the carrier radio-frequency and the voice-modulation band of frequencies. In single-sideband operation, one sideband (e.g., the lower) is suppressed, leaving only the upper, with its carrier. A second voice modulation (fig. 5 [C]), consisting of a lower side-

band whose upper sideband image has been suppressed, can "ride" the same carrier (fig. 5[D]), and the carrier is thus doing double duty. However, the two voice sidebands are not limited to a single conversation; each can carry a number of them, closely packed into the spectrum like teeth in a comb. In addition, any of the voice channels may be further broken down into radiotelegraph channels, like teeth in a finer comb.

2. Television.—Television is an outgrowth of the techniques developed in (1) the transmission by wire of graphic material; (2) the utilization of the cathode-ray tube; (3) the perfection of the motion picture with its synchronized sound track; and (4) radio broadcasting. The period of early television development from 1924 to 1939 was interrupted by World War II, and when work in the U.S. was resumed in 1946, transmission was in the VHF band that had been opened during the war. Coaxial cables were first used for intercity network television in 1946, and microwave radio transmission, using relay towers, began in 1947. The first coast-to-coast television broadcast over a nationwide system of microwave radio relay took place in 1951. Attempts were made, with better technical than commercial success, to introduce television into the UHF band in 1950. See TELEVISION: History of Television.

VII. MICROWAVES AND REMOTE CONTROL

The introduction of microwave radio relay systems after 1950, to replace wires and cable for general intercity communications throughout the world, ranked with any of the previous important developments in radio technology. Dissimilarities in the troposphere and ionosphere, and even meteor trails, came to be used in the propagation of high-power radio waves. Discoveries in solid-state physics brought a number of important developments in ceramics, phosphors and crystals, one of which—the transistor—replaced the electron tube in many of its applications and supplemented it in others. Radio communication took new forms, especially in aviation. Nonlanguage data transmission became important in the control of machines, missiles and space vehicles.

1. Microwaves.—By 1928, short-wave radiotelephony circuits among the principal nations had been completed, and microwave transmissions began in Europe in the 1930s. During World War II, microwave installations in the UHF band were used by military signal units in Europe, and in the United States the first practical SHF microwave radio system for transmitting commercial telegrams was placed in operation in 1945. In 1946 the first radio relay system for long-distance telephone service was reported. Microwave radio techniques were applied in 1950 in France and Germany to public telephone service and in the U.S. to pipeline and railway communication and dispatching. Wave-guide techniques already had been used for antenna feeders and other SHF purposes. Coaxial cables had been tested comparatively with microwave radio relay systems in the U.S. for intercity telephone and television transmission; the microwave systems proved more economical and reliable, and by 1951 the Bell Telephone systems had begun a general adoption of microwave radio. By the end of the next decade, about one-third of the intercity telephone circuits and most television network programs were carried by radio relay links. The transmitter and relay towers were usually located on mountain tops or on tall city buildings and spaced about 30 to 40 mi. apart for line-of-sight transmission.

Antennas and Arrays.—Antennas for microwave service include parabolic reflectors, electron lenses and horns. The size of an efficient antenna depends upon the wave length it is designed to transmit or receive; thus, as higher frequencies came into use, the size of antennas decreased. A familiar contrast is the 500-ft. broadcasting tower and the SHF "whip" antenna for police patrol cars.

Arrays of antennas may be so arranged and fed by transmission lines that they produce strongly directional signal patterns. In the 1960s there was increased use of pedestal-mounted, servo-operated, steerable paraboloid (dish) antennas. Another type was a stationary array of phased elements disposed in the form of crossed combs. The length, spacing and configuration of the "teeth" determined the pattern of the transmitted beam.

Ionospheric and Tropospheric Scatter Propagation.—Thomas L. Eckersley reported in 1932 that cloudlike ionization concentrations in the Kennelly-Heaviside layers might be used to propagate VHF signals beyond horizon distances. D. K. Bailey, of the U.S. national bureau of standards, and several associates reported in 1952 that such propagation was observable over long distances. By 1955 Bailey and his associates reported transmissions of VHF signals through the ionosphere, using radar super-power pulsing techniques.

Henry G. Booker and others developed the hypothesis in 1950 that heterogeneity of turbulent volumes of the troposphere also propagates VHF radio waves beyond the horizon. Thus, it became possible to employ scatter techniques in inaccessible terrain, on sea routes and in the arctic where other radio systems meet unstable refraction conditions. By 1958 a dependable range of 650 mi. had been achieved by tropospheric scatter, using a power of 50 kw. in the UHF spectrum and single sidebands carrying a 24-channel telephone-teletypewriter traffic load. Commercial scatter systems for combined telephony and television were inaugurated in 1957.

Meteor-Burst Communication.—Unseen meteors and meteoric dust particles bombard the earth's atmosphere day and night, often in quantities sufficient to support a type of sporadic radio communication that takes advantage of the propagation scattering effect of a trail of free electrons left in the upper atmosphere by each meteor. Since meteor bursts last only a matter of seconds, messages must be prepared in advance and high-speed data handling systems must be provided. The reflection paths of contact are automatically established by the occurrence of a meteor burst, resulting first in an instantaneous exchange of "trigger" signals between the two stations involved, followed by transmission of the message. When the signal strength falls below a predetermined level, communication is positively terminated so that no message material is lost, and transmission is resumed automatically upon the occurrence of a subsequent burst. Measurements of radar-type signals reflected by meteoric ionization were reported as early as 1948. The technique of applying such reflections to point-to-point radio was considered in Canada, Australia and the United States in 1952 in connection with other types of forward-scatter transmission, and two-way communication of this kind was first achieved in Canada in 1953.

2. Extremely High Frequencies (EHF).—Millimetre and submillimetre waves (4 mm. and less) were undergoing experimentation in the late 1950s, with prospects of great advantages for long-distance communication through multimode wave guides. Dielectric wave guides, containing no metal, were investigated in Germany before 1920, and in Great Britain, the United States and Italy between 1936 and 1948.

At extremely high frequencies the thermal noise inherent in a vacuum tube severely limits the amplification of a very weak signal. The search for a solution to this problem led to a solid-state device called the parametric microwave amplifier in 1957. It consisted of a germanium diode detector, "pumped" at a lower frequency by a miniature pencil-type electron tube, to amplify the signal. Another type of EHF amplification was accomplished in 1957 by the maser (*q.v.*)—an ammonia- or helium-filled oscillator operating at temperatures close to absolute zero. The maser uses a cavity resonator tuned to the molecular resonance frequency of the gas.

John Bardeen and W. H. Brattain introduced another kind of semiconductor in 1948 that became known as the transistor (*q.v.*). They discovered that a metal point resting on a germanium crystal, when emitting a forward current into the crystal, would influence the reverse current in a nearby metal collector point. W. B. Shockley, an associate of Bardeen and Brattain, developed the theory and distinguished the different types of transistor junctions. The 1956 Nobel prize in physics was awarded to Bardeen, Brattain and Shockley for their work in this field.

3. Radiotelemetry for Missiles and Satellites.—The age of rockets and missiles brought with it the need for providing great amounts of information from test flights, so that performance could be evaluated. The process of encoding instrument readings,

transmitting them on multichannel radio circuits and recording the data at ground stations developed into a special engineering field called telemetry. Later, with the advent of artificial satellites, and especially in the case of manned space flights, radio played an indispensable role in controlling orbital paths and relaying back to ground stations data that were obtained outside the Earth's atmosphere.

The transparency of the atmosphere to the passage of UHF and SHF radio waves was verified by reception of radar echoes from the Moon, first accomplished in 1946. By 1958 UHF voice transmission by lunar reflection had been proved feasible, opening the way to communication between any two points on Earth that were simultaneously within sight of the Moon. Extending this idea, successful experiments were conducted in communication by means of signals reflected from artificial satellites as well as signals received and retransmitted by satellites. Plans were under way in the U.S. in the early 1960s for a system of international communication utilizing a number of relay satellites in orbit about the Earth.

VIII. FACTORS AFFECTING RADIO PERFORMANCE

1. Mechanism of Propagation.—When a charge of electrons is guided along a wire in response to the application of an electromotive force to one of its ends, a concentric electromagnetic field (which takes a form roughly analogous to parallels of latitude about the earth's axis) is formed about it, in a direction determined by the familiar righthand screw analogy of electric current. At the same time an electrostatic field is produced whose lines of force (again roughly by analogy like the earth's great circles of longitude) are everywhere at right angles to the electromagnetic field. This twofold field is formed outwardly to great distances from the wire, the wave front of the disturbance, involving collision of electrons in space, moving forward at the velocity of light. In this field is stored the energy of the electric charge on the wire. The combined field should not be thought of as having been established in a static manner. Because the electron flow along the wire takes the form of a wave, there is a building up of potential, a transformation of energy and a reflection from the wire's open end after the manner of a sound wave in an open organ pipe; possibly a second reflection from the opposite end, and so on until the wire is charged and the energy of the charge is completely stored in a steady field.

At this stage, removal of the electromotive force from the end of the wire causes collapse of the field and return of the energy to the wire. In an electromagnet the wire is wound in a coil about an iron core for the purpose of confining the field to a small area. The collapse of the field when the circuit is broken and the oscillating nature of the return of energy to it are made evident by the spark which occurs at the open contacts. In this case the inductive component of the collapsing field is high, the radiation component low. In the antithetical case of a straight antenna wire, the induction field is low and the radiation field is purposely made high. Radiation is promoted—indeed it is made possible—by applying to the antenna continuously reversing polarities of electromotive force, created by an alternator or more often by vacuum tubes or valves oscillating in tuned inductance-capacitance circuits in the transmitter, at radio frequencies (10,000 c.p.s. or more). The rapidity of reversals results in the forming of successive oppositely poled fields before the initial ones have had time to restore, to the antenna to which they were bound, the energy due to the initial fields' collapse. Thus the initial fields are detached and set free to continue onward and outward at the velocity of light in air. At frequencies lower than those used in radio, such detachments of energy are entirely insignificant. Even at radio frequencies there is little radiation from a transmission line electrically balanced with respect to the earth, consisting of a pair of parallel wires, closely spaced, fed simultaneously with opposite polarities; such low-loss transmission lines are often used to conduct power from transmitters to certain types of antenna proper. Radiation does occur when the parallel wires are moved apart or to an angle with each other; maximum radiation occurs under conditions of maxi-

mum unbalance, which is the general condition of an aerial or antenna wire in vertical relationship to the horizontal plane of the earth's surface. Another condition of unbalance is represented by the doublet, or dipole, consisting of a straight wire or rod fed from a discontinuity at its middle. In both these cases, controlled unbalance may be said to have produced effective coupling of guided power in the transmitter and antenna to the medium of propagation—that is, the transformation to radiated power is efficient. Receiving antennas and receivers are also effectively coupled to the medium of propagation by the same considerations of design. In fact, except for complications of economics, site limitations, the direction of arrival and polarization of the wave front and the necessity to discriminate between the wanted signal and interfering signals, sending and receiving antennas are alike in form and purpose and by the theorem of reciprocity are interchangeable.

The respective functions of transmitters and receivers is to emit and extract power to and from the medium of propagation. At the point of reception, the transverse wave associated with each ray of propagation may be represented by electrostatic and electromagnetic vectors lying at right angles in a plane normal to the ray, the electrostatic field being measurable in terms of potential gradient (microvolts) per unit of wave-front length (the metre), as applied against the effective height of the receiving antenna. In free space, away from complications resulting from proximity to the earth and from the constitution of the earth's atmosphere, the receiving field intensity can be calculated in terms of the current in the transmitting antenna, the frequency or wave length of the electromagnetic disturbance and the distance between transmitter and receiver. In the case of low frequencies at all distances, mathematical calculations can give useful figures of field intensity as foundation for further consideration of the variables of the transmitting medium.

Sky Waves.—Much effort has been expended by researchers in theoretically establishing, examining and measuring the now well-understood complexities of the propagating medium. The original Kennelly-Heaviside concept of stratified ionization of the upper atmosphere has been expanded to account for the observed and measured behaviour of radio sky waves. When solar radiation impinges upon the atmosphere from above, it is absorbed unequally at various levels, giving rise to the formation of layers with differing refractive (hence reflecting) properties. In the process of absorbing solar radiation, electrons are detached from gas molecules. The density of the electrons during the daytime and the rate of their recombination with the ionized particles at night determine the changing usefulness of the layers to return radio waves to the earth. Several successive layers are postulated, each characterized by partial inversion of the vertical gradient of ionization density, with the highest value in the mid-position of each layer. The layers have been given designations and their approximate virtual daytime elevations above the earth's surface have been determined as follows: D, 50–90 km. (30–55 mi.); E, 110 km. (70 mi.); F₁, 175–200 km. (110–125 mi.); F₂, 250–400 km. (155–250 mi.). Ionization density is greatest in the outer F₂ and least in the inner D layer. At night the D layer disappears and F₁ loses its identity by combining with F₂ at 300 km. (185 mi.). Sunset and sunrise produce diurnally unstable conditions, as the layers rise and fall. Ionization and height vary also with the seasons and with latitude, in accordance with the altitude of the sun and duration of the hours of daylight. While all layers absorb some energy of the wave front by electron collision in the process of refraction, the air density in the D layer produces absorption with little refraction. In the other layers, propagation is best at night, and attenuation of high-frequency signals by absorption in the daytime increases sharply as the frequency used is lowered.

Double Refraction.—Because of magnetoionic interaction between the earth's magnetic field and the free electrons whose progressively increasing density refracts radio waves, the latter undergo double refraction and are split into two elliptically polarized components. The refraction indices and the absorption of the medium are both different for the two, so that a somewhat unstable, emergent resultant wave exhibits elliptical polarization. This has negligible effect upon the handling of message traffic, but

does adversely affect the degree to which direction finders yield correct bearings for navigational purposes.

Critical Frequencies.—Important to the course which radio waves take through the refractive layers is the discrimination offered to their transit by virtue of their frequency. As frequencies are increased, experimental waves directed straight up toward the zenith have been found to require ever higher electron densities if they are to be reflected downward. There is a critical frequency, f_o , higher than which the waves will pass on through the layer and not be returned. This property of frequency discrimination is still effective when the angle of incidence, θ_o , is changed from the experimental 0° at vertical incidence to its practical value, θ , shown in fig. 6. Here the wave passes from point of transmission T to point of reception R through refraction along the arc BAC within

FIG. 6.—RADIO WAVES, SKY PROPAGATION (see TEXT)

a layer having an effective height of FE. The highest frequency which will travel the course TBACR has been called M.U.F., the maximum usable frequency for distance TR, height FE and the electron density in the layer. The M.U.F. bears to f_o the relationship: $M.U.F. = f_o \sec \theta$. Government laboratories make available to radio station technicians graphs and nomograms predicting what M.U.F. will be under given circumstances, taking into account f_o , the time of day at longitude of FE, the latitude of FE, the season of year, conditions related to the 11-year cycle of sunspot maximum, the electron density and distances approximating TR and height FE. Transmitting station T will use if available an optimum working frequency of about 85% only of the M.U.F. to afford leeway for approximations used in the predictions and for propagation abnormalities. It is evident that if the frequency used exceeds M.U.F., the signal will follow the straight line TBF and be lost to R, instead of taking the trajectory TBACR. On the other hand, if the working frequency is reduced too much, the layer will absorb too much of its energy; signal strength at R will be too low, or an uneconomical power level will be required at T. The lowest useful high frequency, called L.U.H.F., is roughly half the M.U.F.; its calculation is complicated by variables connected with receiving conditions.

Modes of Transmission.—Fig. 6 depicts what is known as "one-hop" transmission from T to R. If R were twice as far removed from T, the same frequency could be used in two-hop propagation. As a matter of practice, two-hop and three-hop propagations are common and offer no difficulties compared with single hops so long as conditions in the reflecting layer are uniform. Along great circles of the earth, like meridians, which do not cut through the ionospheric transitional effects of sunrise and sunset, multihop transmissions girdle the globe, not only once but several times, and have required that special precautions be taken to prevent unwanted "echo" signals.

Skip Distance.—Assume that in fig. 6 the transmitter is emitting the M.U.F. but that the wave, as is ordinarily the case, is not the single ray TB but a rather wide solid cone of rays with apex

at T, fanning out a few degrees with TB as an axis. Confining attention to the plane of the paper, all the rays in the cone to the right of TB will be reflected and fall at points to the right of R. All the rays to the left of TB (by definition of M.U.F.) will pass through the layer unreflected. No signals will reach the ground between T and R from the sky. TR is the skip distance. If the antenna at T is omnidirectional, TR defines the radius of a ground circle about T lying within the skip distance associated with the M.U.F. used.

2. Propagation Variables.—In relation to its medium of propagation, telecommunication has to concern itself not only with the fairly stable complexities which have been described but also with instabilities. For at times the refracting ceilings which the layers present to radio waves from below are almost mirrorlike and still, at other times they undulate, giving rise to shifting transmission paths that change phase interference relationships and polarization of wave fronts at points of reception. Again, especially in the auroral regions, extending 23° in radius about the earth's geomagnetic poles, and particularly around times of the equinox, ionization, also giving rise to aurora polaris, causes severe turbulences and abnormal absorption in the ionosphere. The earth's magnetic field converges on the arctic regions, leading charged particles from the sun to bombard them. The F_2 layer, especially, is adversely influenced during periods of abnormal earth currents. A statistical correlation has been observed between high sunspot numbers, the location of spots on the sun's limbs, the period of rotation of the sun on its axis and poor sky-wave propagation due to effects of extraordinary ultraviolet radiation into the upper atmosphere. A more recent theory identifies sunspots, earth currents, aurora and ionospheric turbulence as concurrent effects that find a common cause in critical juxtapositions of planets in the solar system. Sudden solar flares or eruptions, accompanied by direct ultraviolet radiation which reaches down into the low D layer on the light side of the earth, results in abnormally high absorption in that layer, whose normal characteristic is to absorb, rather than to refract, wave-front energy. The result is radio blackout, lasting minutes to hours, to which the names Dellinger effect and SID (sudden ionospheric disturbance) have been applied. Radio communication using sky-wave propagation is stopped for the duration of SID because of the inability of radio waves to reach the E and F layers.

Sunspots rotate with the surface of the sun and thus exhibit a periodicity of 27 days in repeating their influence upon radio transmission. The number of sunspots varies over an uneven 11-year period.

Sporadic Transmission.—Not all the variables of the atmosphere are adverse to the propagation of radio waves. Some of them make possible transmissions which otherwise would not occur. One has been given the name Sporadic E, to designate what behaves like a cloud stratum of ionization, E_s , with a "blobby" subsurface from which propagation is neither by refraction or reflection but is the summation of contributions of scattering, by secondary emission, from a multiplicity of sources closely spaced. Because integrated, such sources may give reliable transmission of very high frequencies below 150 mc. if the beam is aimed nearly tangential to the earth's surface. These transmissions are at frequencies exceeding the M.U.F. of the E layer. They are at a maximum in summer and in zones of visible aurora. Unlike refraction, the mechanism of scattering transmits in all directions from the ionized layer. This may cause direction-finder inaccuracies if, unknown to the manipulator taking a bearing, he happens to be standing within the skip zone of the transmitter. In that event he will be receiving the transmitter's signal not upon the observed bearing of a primary source but upon that of a secondary, scattering source located at some point in the E_s zone having no valid geographical relationship to the point of primary signal emission. The error may amount to 180° .

In the heterogeneous troposphere there exist, as a result of air turbulence, eddies demonstrating deviations from mean dielectric constants (and hence refractive indices) with which they are surrounded. These discontinuities produce scattering effects that at times cause abnormally strong signals, at others abnormally strong interference. In the troposphere, also, where the very high fre-

quencies are transmitted, the air may stratify as to its quasi-optical refractive index, under meteorological influences, in such a way that radio waves are either led along a plane of maximum index between layers of lower index, or are confined between a layer and the earth. In either event, being trapped as though in a duct or wave guide leading over the horizon to distances beyond line of sight, attainable distances of communication are increased. Some observed instances have proved amenable to wave-guide analysis.

Diffraction.—Somewhat akin to scattering is diffraction, the bending of super-high-frequency waves around an obstacle, building or the protuberance of the horizon, thus increasing the service range of a transmitter. The intersection of the beam with the horizon defines a point above which the atmosphere may be thought of as a radiator of secondary emissions. In microwave beam practice, passive reflectors are sometimes employed to make definitive the jumping of an obstruction in lieu of diffraction.

3. Interference.—Proper reception of radio signals depends upon ability to receive wanted signals that are stronger than unwanted signals and accompanying noise. Another station using the same frequency in a different part of the world is an example of an unwanted signal. Another instance is a station whose frequency has been assigned so closely to that of the wanted signal that the harmonic content of the unwanted signal overrides or beats with the wanted wave. If the interference is caused by the interfering station's exceeding its authorized tolerance for frequency drift, the remedy lies in having the offending station put back on its assignment. Assuming the interfering station to be on its proper frequency, unless the situation can be cured by use of directive receiving antennas, relief must be sought from the authorities who made the assignments. Regulatory authorities have adopted and enforce standards of frequency departure tolerances, maximum harmonic content of emitted waves and authorized maximum power to be employed, in order to keep interfering signals within practical control. Based upon these factors, with additional allowances for filter inefficiencies and frequency drift inherent in receivers, the widths of bands for all types of emission and modulation rates have been specified on a worldwide pattern.

Among the types of interference sometimes encountered for which there is no ready remedy at the receiver is cross modulation. When a powerful transmitter's wave strikes the ionosphere, the free electrons, which determine the dielectric constant and therefore the effect of refraction, are agitated to collide with ionized molecules at rates varying from high to low in accord with the wave's modulation. The wave front from another transmitter, striking the agitated layer at that point and at that time with a modulation pattern of its own, will be subjected to cross modulation from the more powerful wave.

4. Signal-to-Noise Relationships.—If a received signal is clear of interference from unwanted signals, its field strength can be amplified to any degree permitted by the thermal noise and vacuum tube shot effects in the initial stage of the receiver. These place a final limitation upon amplification, but serve to limit it only in the very high-frequency and super-high-frequency bands where other forms of interference are absent. All efforts at the receiver are therefore bent upon improving signal-to-noise-level ratio, S/N. The three avenues of approach are to improve S, to mitigate N or to introduce some distinguishing characteristic into S at the transmitter (frequency or phase modulation, for example) so that the receiver will be more responsive to S than to N.

Improvement of the signal may be achieved by increasing power at the transmitter, by choosing a type of modulation such as pulse-position modulation in which bursts of high power are obtainable without overloading vacuum tubes, by adopting directive antenna arrays or by frequency-diversity transmission. At the receiver many manipulations are possible, including choice of suitable space-diversity antennas, crystal-driven stabilizers and filters designed to accept all possible power of the carrier and its necessary sidebands and harmonics and to reject all other signals.

Antenna Gain.—Modern antennas for nonmobile use are designed to favour concentration in azimuth, or direction toward the correspondent station, of as much as possible of the transmitter's power. They are of two general classes: antenna arrays and

wave antennas. Arrays take advantage of interference between two, three or more like antenna structures so placed with respect to wave length and the line of desired propagation that their power adds in the forward direction and cancels toward back and sides. In a receiving array this results in desirable discrimination between a wanted signal and an interfering disturbance or signal arriving from a different direction. The power advantage which an array or other form of directive antenna achieves is called the antenna's gain. It is greatest for multielement VHF arrays and SHF reflectors and lenses. A wave antenna is generally less effective in concentrating its beam than an array, but in the larger forms associated with the lower frequencies it has economic advantages and will effectively handle a 2:1 ratio of frequencies. Some large wave antennas are steerable in range. Such a steerable antenna is in the shape of a rhombus or diamond floating on pulleys attached to four poles and so arranged that if the short diagonal is purposely altered in length by force applied through the pulleys, a counterweight will correspondingly adjust the length of the long diagonal, keeping the antenna taut. The antenna wires at one end of the long diagonal are connected to the station feeder; wires at the opposite end terminate in resistors. When the long diagonal is altered, the angle which the sky wave, emitted from it, makes with the earth plane is modified. By manipulation of antenna configuration, therefore, the vertical angle of the wave's departure can be aimed at the point of reflection in the ionosphere. If the long diagonal was put in proper azimuth when the supporting poles were set, the beam will fall directly upon the point of reception. There an array of similar rhombic antennas a mile long may be lined up along the path of propagation for phasing and integration of their outputs, some having been steered low on the horizon to receive the one-hop mode of propagation and others steered higher to respond to other modes.

Fading.—Of the variables in propagation encountered in maintaining received signal strength at a high level, fading is the most widespread and serious. The term fading is broad enough to comprehend temporary loss of field strength at a receiver for any cause associated with the medium of transmission. Already discussed have been the common causes of fading experienced by waves taking any one path between transmitter and receiver. There remain to be considered the complications arising when a wave front takes more than one path at a time. By the same principles of wave interference met with in the study of optics and sound, if the wave front be reflected at two or more points and the reflected rays arrive at the receiving antenna in phase, their effects will add and the signal will be strengthened; if the rays arrive 180° out of phase, their effects will cancel and the signal will disappear; if the out-of-phase condition takes an intermediate value, there will be a corresponding change of signal strength. This phenomenon is evident whenever the ground wave interferes with a sky wave; when two sky waves take modes of propagation involving a different number of hops; or when one of the modes is along a layer, or between two layers; when, in communication between two airplanes in flight or between two beam radio towers, a direct wave beats with another reflected from the ground or from air-layer interfaces caused by temperature-density inversion; or when the arrival waves have taken different routes in the horizontal plane; or one in the horizontal, the other in the vertical; or when polarization rotation occurs in a different manner or to different degree over two routes, or is caused by double refraction. Fading of all these types is called multipath interference. It is rare at very low frequencies. At other parts of the spectrum the fading occurs in cycles whose rapidity increases from around 60 times an hour at 1,000 kc. up to millions of times a second in the SHF and EHF bands. This rapid increase in the fading rate as transmitted frequencies are raised explains the occurrence of selective fading within sidebands so wide that the effects at the top of the sideband do not coincide with those at the bottom. The discovery that fading of a received signal does not occur simultaneously at two points that are three to ten wave lengths apart led to the invention of space-diversity systems of reception. The outputs of separated antenna-receiver systems, equipped with independent automatic volume controls and tuned to the incoming wave, are fed into a common mixing and

limiting system that delivers a substantially constant signal to the terminal apparatus, even during periods when the fading is severe.

5. Radio Noise.—Industrial Noise.—Upon the assumption that in achieving the best possible signal-to-noise (S/N) ratio everything has been done to favour S, the qualities of N remain to be examined. Noise may be divided into two categories, man-made and natural. Man-made or industrial noise is greatest in the cities, least in rural or isolated localities. The latter are therefore preferred for receiving sites. The chief cause of man-made noise is electrical circuit transients which cause radiation from portions of circuits where sparks occur. Switches, motors, ignition systems are offenders; so are X-ray apparatus, diathermy machines and industrial precipitators, high-frequency heating and other equipment employing radio frequencies. Mitigation at the receiver is difficult. The use of directive antennas, wave traps and narrow-band receiver filters is sometimes effective. Usually the correction of industrial noise conditions is sought at their sources, by shielding or isolating radio-frequency circuits.

Atmospherics.—Noise from natural sources, entering the receiver by way of the antenna and affecting the receiver output in the same way as amplitude-modulated signals, takes two forms: atmospheric and extraterrestrial. The super-high-frequency band (centimetre waves) is the only one free from both forms of extraneous noise; so that in that band, receiver thermal (or resistance) noise alone limits the amplification level. Atmospheric noise, or static, is the characteristic natural interference which has to be dealt with in radio. At point of reception it represents the integration of the field strengths there apparent from nearby and distant thunderstorms going on within signaling distances, transmitted by means of ground wave and sky waves of all modes in accordance with the same laws which govern signal propagation. Atmospherics are at a maximum at night on account of sky-wave transmission from great distances. They are stronger in summer than in winter, weaker in high latitudes than in the tropics. Their sources are concentrated somewhat in geographical areas like the eastern Caribbean sea, where median values of field strength are shown by measurement to be high. Directive antennas are frequently oriented to discriminate between direction of arrival of atmospherics and the wanted signal.

Since natural atmospherics, like man-made disturbances, contain random frequencies over a wide band, filters are introduced into receivers to reject sharply all noise except the components necessarily admitted with the signal sidebands. Amplitude limiters are also used.

Extraterrestrial Noise.—Extraterrestrial noise interferes with radio telecommunication in the very high-frequency band (metric wave lengths) and down to 20 mc. There its strength is, roughly, 20 times the thermal noise in the receiver. It is attributable to influences classified as galactic (stellar or cosmic), solar and meteoric. Galactic noise is at a maximum from the direction of the region of Scorpio and Sagittarius, in the galactic centre of the Milky Way.

Solar noise is of lower field strength than galactic noise at frequencies below 30 mc. but is appreciable at 100 mc. and more. Like cosmic noise it is of random nature, fairly constant in amplitude except at times of abnormal solar disturbances. At such times its strength, at 100 mc., may exceed galactic noise. Solar noise increases are often concurrent with other effects of solar eruptions already mentioned—the influence of ultraviolet light in increasing D-layer absorption of radio-wave energy, and turbulences in the E and F layers which make them temporarily incapable of refraction and reflection. See RADIO ASTRONOMY.

IX. USE OF THE RADIO-FREQUENCY SPECTRUM

The value of the radio spectrum depends upon the skilful management of this natural resource. Radio waves recognize no political boundaries and therefore hold the threat, unless controlled, of interfering with radio operations in neighbouring and even far distant countries. Governments enforce within their own territories agreements upon such matters as call signs for identification; allotment of frequencies to specified services; limitations upon the type of emissions (modulations), bandwidths and power

which may be employed; and specifications leading to full occupancy of each band.

1. Frequency Sharing.—Congestion makes it necessary to adopt expedients for making maximal use of the various available frequency channels by assigning a single frequency to simultaneous use in different parts of the world, and by requiring stations to share their frequencies with others, to take advantage of differences in time zones or paucity of traffic to be handled. The urge to conserve spectrum space is made evident, in large transoceanic radiotelegraph operations, by the practice of assigning a single transmitter to cover the requirements of more than one circuit. Such forked use of a transmitter will cover from 1.5 to 2.0 channels of communication. On the most important circuits two transmitters are often allotted for dual operation, so that if transmission on one fails, service will not thereby be interrupted. Pairs of frequencies in a station's complement are also involved in dual emission on most circuits during twice-daily periods of transition between optimum uses of either wave.

2. Modulations, Bandwidths and Tolerances.—The bandwidth occupied in the spectrum by any emission depends upon the type of modulation, being narrow for hand-keyed Morse telegra-

TABLE I.—Radio Emissions and Their Bandwidths

Purpose and modulation	Emission type	Typical bandwidths (kc.)
Amplitude Modulation		
Telegraphy, hand-keying	A 1	.06-0.1
Telegraphy, four-channel multiplex	A 1	.85
Telegraphy, audio-tone	A 2	2.1
Telephone, double-sideband (DSB)	A 3	6-8
Telephone, single-sideband (SSB)	A 3	3-4
Broadcasting, clear-channel	A 3	10
Broadcasting (depending upon quality)	A 3	8-20
Facsimile	A 4	5
Television	A 5	4,000-9,000
Frequency Modulation		
Telegraphy, Frequency shift	F 1	1.4-1.7
Telephone and broadcasting	F 3	36
Facsimile	F 4	25
Pulse Modulation		
Radar	P 0	40,000

phy, considerably wider for voice broadcasting and very wide for television. Bandwidths are therefore specified in accordance with emission types. A bandwidth may be considered the minimum safe separation between adjacent carriers so modulated. It includes the "guard-band" protection necessary to prevent overlap of its fundamental and harmonics with those of adjacent channels, if frequency deviations are held within specified tolerances. Except for single-sideband (SSB) operation, the band is considered as bisected by the assigned frequency of its carrier.

The types of emissions permitted and bandwidths specified in the international regulations annexed to the Buenos Aires convention of 1952 are shown in Table I.

Radio transmitters must maintain assigned frequencies within narrow limits. For broadcast stations the deviation or drift tolerance is 20 c.p.s., which is .002% at 1,000 kc.—a narrow tolerance. In general, a powerful station is allowed a tolerance only half that of a weaker station; a ship five times the tolerance of a coastal station; and a fixed station working in the congested international short-wave band (0.003%) less tolerance than a long-wave station (0.005%). Lifeboats, ships' emergency transmitters and survival craft have the widest latitudes (0.5%). Drift tolerances have narrowed as pressure for spectrum space brought improved means for controlling frequencies.

3. Division of the Spectrum.—Table II indicates the useful

TABLE II.—Uses and Ranges of Assignments

Frequency	Principal media	Principal uses	Most useful ranges
10-500 kc. low frequencies	Ground wave D layer E layer	Maritime Navigational Military	More than 1,000 mi.
500-3,000 kc. medium frequencies	Ground wave E layer F layers	Broadcasting Navigational All uses	0-1,000 mi.
3-30 mc. high frequencies	F layers	Television Aviation Mobile	All distances
30-1,000 mc. ultraionospheric	Ground wave Troposphere	Aviation Broad band Radar	Over horizon
More than 1,000 mc. microwave	Troposphere		Quasi-optical

range of communication in various parts of the radio spectrum, a list of uses to which the parts are assigned and the Kennelly-Heaviside layers involved in propagation.

The radio spectrum was arbitrarily divided as shown in Table III by the Atlantic City (N.J.) convention of the International

TABLE III.—Subdivisions of the Radio Spectrum

Group	Frequency denomination	Abbreviation	Frequency range (mc.)	Wave-length denomination	Wave-length range
1	Very low	VLF	Below .03	Myriametric	Above 10 km.
2	Low	LF	.03–.3	Kilometric	1–10 km.
3	Medium	MF	.3–3	Hectometric	100–1,000 m.
4	High	HF	3–30	Decametric	10–100 m.
5	Very high	VHF	30–300	Metric	1–10 m.
6	Ultra-high	UHF	300–3,000	Decimetric	10–100 cm.
7	Super-high	SHF	3,000–30,000	Centimetric	1–10 cm.
8	Extremely high	EHF	Above 30,000	Millimetric	Below 1 cm.

Telecommunication union (1947) in order to facilitate orderly consideration of its parts. The transmission properties of these groups differ widely. The table shows the active radio spectrum subdivided into eight groups. The first three—VLF, LF and MF—were used before 1925, the HF band before 1939.

Low Frequencies.—Groups 1 and 2 in Table III, the VLF and LF or ground-wave ranges, alone are capable of following the curvature of the earth. These ranges, called collectively terrestrial radio, are therefore used for long-distance communications as well as for navigational radio.

In the absence of any available alternative, VLF and LF radio-telegraphy was the favoured method for transoceanic use prior to 1927. After that year it rapidly gave ground to transmission on higher frequencies, but served as stand-by to protect short-wave circuits, especially where routes cut the auroral zones that exist around the earth's geomagnetic poles. Even this utility largely disappeared when, around 1946, electrical relay points located in or near the tropics were found capable of dividing east-west circuits between terminals into two coupled links, the one availing itself of relatively dependable north-south transmission, the other conducting the east-west circuit components through the tropical belt where auroral zones could be by-passed.

The longer VLF and LF waves interested Marconi and other early workers in transoceanic wireless telegraphy because of the results, measured in working mileages, that they yielded. Transmission is dominated by a ground wave propagated to distances up to about 1,000 mi., plus a relatively stable mode of multiple mirrorlike reflections between the two concentric spheres consisting of the earth's or sea's surface and the troposphere and low ionosphere. These act as an effective and efficient wave guide. The rate of decay of the ground wave depends upon the conductivity and dielectric constant of the ground; except for the very lowest frequencies and extreme distances the decay rate is less over water than over land. The wave-guide effect tends to conserve signal strength over global distances. Except for sunrise and sunset effects, fading of signals is not a factor with long waves. The three chief drawbacks to long-wave operation are: the prevalence of noise and static (lightning disturbances are also propagated to global distances by the wave-guide mode of transmission); the requirements of large amounts of power to radiate from an antenna at the very low frequencies and to override the static; and the necessity for building large, high and consequently expensive antenna structures. VLF waves are generally not suitable for telephony because of the low ratio of the modulation to the carrier frequency.

Medium and High Frequencies.—MF transmission, Group 3 of Table III, occupies a mid-position between ground-wave and sky-wave propagation and is best understood by reference to conditions in adjacent bands. The lower part of the band found early use in ship-to-shore wireless telegraphy. Antenna sizes and power requirements are adapted for marine work; distances workable, however, are shorter than for high frequencies. The middle part of Group 3 is reserved for broadcasting. Its characteristics are well known to the public, a ground-wave service area of greater or less extent depending upon power assigned and a night area served by sky-waves subject to fading. Static conditions are moderate. Beaming of antennas and sharing of hours of operation among

stations are practices that prevent mutual interference and increase public service.

Group 4, the high frequencies or short waves, are transmitted over global distances by multiple-hop refractions through the ionosphere. The HF band is one of the most crowded portions of the spectrum. It is generally true that ionospheric transmission ceases to be practical beyond 30 mc.

Higher Frequencies.—Groups 5 and 6 of Table III, VHF and UHF, the metre and decimetre waves, were extensively investigated during World War II. VHF transmission is primarily limited to line of sight, but it is stable and suitable for such uses as television broadcasting. With the advent of UHF transmitters of very high power, a new type of UHF transmission called UHF scatter propagation, was discovered. This effect was largely attributed to wave refractions in the troposphere (altitudes below 10 mi.). UHF scatter permitted the reception of weak but stable signals far below the horizon. Television transmission over several hundred miles by means of scatter propagation was accomplished in 1953.

Super-High Frequencies.—Group 7 (centimetre) frequencies are often referred to as microwaves. While Groups 6 to 8 are all quasi-optical, Group 7, SHF, is particularly adaptable to quasi-optical devices such as focusing antennas using parabolic reflectors, dielectric lenses and horns for concentrating and directing narrow beams of communication power. Expansion of use of this band was a spectacular development of the 1950s. Because of their extremely high carrier frequencies, microwaves furnish an ideal medium for such high-speed communication as multiplex telegraphy and telephony and television relays.

Microwave beams at 4,000 mc. (7½ cm.) have been used in the U.S. transcontinental television network, relaying video signals and hundreds of telephone channels from coast to coast. At an average span of 25–30 mi. between stations, more than 130 repeaters were used in each direction. Most of these relay stations were fully automatic and were installed in unmanned shelters, some accessible only from the air. A telegraph microwave is similar. Working on a frequency of about 4,000 mc., its paraboloid reflectors behind dipole antennas are located at the tops of towers and within line of sight over the horizon. Changes in the atmosphere seldom attenuate the signals beyond the ability of terminal equipment automatically to compensate, and diversity reception makes the outage record all but perfect. The frequency is not high enough (as at 10,000 mc., for example) to be interfered with by effects of scattering from hail, raindrops or snow; nor in the region of 0.5- to 2-cm. wave length where resonance of particles in water vapour, clouds and oxygen gas interferes. Again, 4,000 mc. is not low enough to be affected by atmospheric or industrial noise. The limiting transmission factors are the thermal agitation and vacuum tube shot effects in the first stages of the receiver, made troublesome because they are amplified along with the received signals. Transmitting power tube output is the order of one-tenth watt to ten watts. Double-frequency modulation is employed, the sub-carrier being one megacycle. Signaling intelligence occupies the broad band from 30 cycles to 150 kc., accommodating 32 voice-frequency bands each capable of transmitting 16 teleprinter (or 32 multiplex printer) telegrams per minute.

The EHF or millimetre waves were at the forefront of radio research in the 1960s, and EHF held great promise for long-distance communications. Millimetre waves can propagate with low loss per mile through straight, hollow pipelines, if the so-called circular-electric mode is set up in the lines. In this mode, the lines of the electric field close upon themselves without touching the wall of the guide. In this way, wall currents in the guide are avoided and losses actually decrease with increasing frequency.

4. Radio Spectrum Management.—International agreements on radio take the form of conventions and annexed regulations. Like other treaties under international law they are, in general, binding only upon the ratifying states. Nations are not bound to attend the conferences. Delegations are not bound to sign. In signing they may take reservations that release them from particular provisions. Sovereign states may refuse to ratify, or in ratifying may also take reservations. Nevertheless, so greatly

does national advantage lie in international co-operation in the radio field, and so unlikely is it that any other method will prevent chaotic conditions in the radio spectrum, that refusals to sign or ratify are rare. By ratifying, a state agrees to pass laws to enforce the provisions of the treaty, subject to its reservations.

International Telecommunication Treaties.—The first radiotelegraph conference of an international nature was called by invitation of the German government in Berlin in 1903, seven years after Marconi's successful demonstration of wireless. This preliminary conference produced the initial draft of an international convention, which was considered, revised and signed by delegates of 27 nations, together with its annexed Radio regulations, at the Berlin Radiotelegraph conference of 1906. At that time the Radiotelegraph union was formed, a governing body modeled after the International Telegraph union, which since its formation at Paris in 1865 had been responsible for the Telegraph convention and the International Telegraph regulations. The London conference of 1912 revised the convention and the regulations. The Washington Radio conference of 1927 inaugurated the subsidiary International Radio Consultative committee (C.C.I.R.), to take its place beside the already functioning consultative and exploratory technical committees on telegraph (C.C.I.T.) and telephone (C.C.I.F.); it also initiated an action, supplementing that of the International Telegraph union (Paris, 1925), to amalgamate the Radiotelegraph and Telegraph conventions. This objective was accomplished through creation of the International Telecommunication union at Madrid, Spain, in 1932, which codified and combined the 1875 Telegraph and the 1927 Radiotelegraph conventions. The regulations annexed to the Telecommunication convention were drawn up separately by a telegraph-telephone conference and by a radio conference at Madrid, as they were again at Cairo, Egypt, in 1938.

The Madrid convention and the Cairo Radio regulations were revised at Atlantic City in 1947, at Buenos Aires in 1952 and at Paris in 1959; the Cairo Telegraph regulations were revised at Paris in 1949, with the United States a signatory to telegraph regulations for the first time, and again at Paris in 1958.

Agreements on Frequency Spectrum.—The history of the radio and telecommunication conferences after 1927 traces the shifting emphasis from marine radiotelegraphy to the later wide diversity of telecommunication. The complexity of making frequency allocations to users increased exponentially over the years despite the expansion of the usable spectrum into the upper frequencies.

The Washington conference was the first to produce a comprehensive frequency allocation table covering services other than marine. Its work was carried on at the Madrid, Cairo and Atlantic City conventions. As a result of work at Madrid, an official list of frequencies was produced, showing, among other things, the date of notification to the bureau of the ITU at Bern, Switzerland, of each use of each frequency and the date each service commenced, as a basis of establishing priority rights to such use. At Atlantic City in 1947 the delegates were faced with the *de facto* aftermath of World War II, during which the use of radio had expanded at an unprecedented rate under circumstances of enforced inactivity of the Bern bureau.

International Organization.—By the early 1960s there were about 100 member states in the International Telecommunication union. Headquarters had been with the United Nations at Geneva, Switzerland, from 1948, when the former headquarters arrangement at Bern with the government of Switzerland was terminated. The ITU became a specialized agency of the United Nations by resolution of the UN general assembly, Nov. 15, 1947.

The International Scientific Radio union, with headquarters in Brussels, Belgium, is a member of the International Council of Scientific Unions (ICSU), a nonpolitical world organization of scientists maintaining relationships with the United Nations and its specialized agencies, particularly UNESCO. ICSU embraces several fields of science, including radio.

Domestic Regulation.—In accordance with the international conventions, every important country enacted domestic legislation to enable the international provisions to be enforced. In Great Britain and Northern Ireland, control was in the hands of the post-

master general, by virtue of the Wireless Telegraphy act of 1904, subsequently renewed each year. The application of the act to shipping is regulated under the Merchant Shipping (Wireless Telegraphy) act, 1919, and the rules made by the board of trade under this act. In Jan. 1947 the British government, in harmony with other nationalization programs, purchased the assets of the British company which from 1929 had represented the merged international telegraph interests of cable and wireless; in the self-governing dominions similar action was taken. The government-owned operating company continued in control of operating the worldwide network until April 1950, when operations and assets in the United Kingdom were transferred to the British post office. In 1952 the post office put its international telecommunications under an external telecommunications executive.

In the United States, commercial radiotelegraph services are operated by private enterprise, regulated by the Federal Communications act of 1934, as amended in 1943. The law is administered by an appointive group of seven members constituting the Federal Communications commission. Among the features regulated by licences or rules of the commission are: assigned frequencies of transmission, tolerances of departure from assigned frequency, types of emission, transmitter power, specifications of performance relating to distortion and interference, hours of operation and qualification of operators and technicians.

RADIOACTIVITY, the property exhibited by certain types of matter of emitting energy spontaneously, was first reported in 1896 for a double salt of uranium and potassium. Very soon it was found that all uranium compounds, and the metal itself, were similarly radioactive. Intensity of activity was proportional to the amount of uranium present (chemical combination being of no consequence) so the effect was attributed to the individual atoms of that element. In 1898 thorium was found to be radioactive in a similar sense: all compounds studied exhibited the property in proportion to their thorium content.

Before these discoveries the position of thorium and uranium in the periodic table of the elements had been strangely anomalous (see PERIODIC LAW). The table had listed in almost regular sequence about 75 elements from hydrogen (atomic weight 1) to bismuth (atomic weight 209); beyond bismuth the sequence had been broken and, after a gap of six or seven places, the list had ended abruptly with thorium (atomic weight 232) and uranium

(atomic weight 238). Prior to these discoveries there seemed to be no common property by which these two elements could be distinguished from the rest. When uranium and thorium, out of all the known elements, were found to be radioactive, a significant distinction appeared possible for the first time. By 1914 the gap between bismuth and thorium had largely been filled with newly discovered elements polonium, radon, radium, and actinium, also radioactive, and four vacant places at the head of the table had been filled. Understandably, opinion was growing that radioactivity was peculiar to the elements of very great atomic weight. Apart from trivial exceptions, nothing was reported until the 1930s to contradict this view. Up to that time studies in radioactivity involved the heavy elements almost exclusively.

The early study of the radioactivity of the heavy elements led to revolutionary changes in ideas of the structure of matter. At the beginning of the 20th century the theory that matter is constituted of atoms was generally accepted by men of science; notions of the inner structure of atoms were entirely speculative. The study of radioactive processes and radiations led, by 1903, to the realization that atoms are not necessarily permanently stable. By 1911 the conclusion emerged that (as far as mass is concerned) the atom is mostly emptiness, almost all of the mass being concentrated in a nucleus occupying roughly $\frac{1}{100,000,000,000}$ (10^{-12}) of the total volume. Next came the important concept of isotopes (1913); and in 1919 transmutation, the modification of an atomic nucleus, was achieved in a laboratory experiment. Finally, the neutron (*q.v.*) was identified as a product of transmutation (1932). With this last discovery, the science of nuclear physics entered its so-called modern phase; acceptable theories of nuclear structure became possible, and the large-scale release of nuclear energy was achieved (1942). By the 1960s practical exploitation of the discovery of the neutron had effected greater changes in world affairs than had been wrought over more than twice as many years by the only other comparable exploitation—that of the discovery of the electron (*q.v.*; 1897).

Early in 1934, it was discovered that radioactivity could be induced in ordinary matter by transmutation in a man-contrived arrangement. In these first experiments radioactive varieties of nitrogen, aluminum, and phosphorus were identified; within a few months it had been shown that neutrons could effect transmutation, and the list of newly discovered radioactive species covered the whole range of known elements, from hydrogen to uranium. At this early stage (1934) there were indications that radioactive isotopes of transuranium elements (those of atomic number greater than that of uranium) might be obtained through transmutation, but it was not until 1940 that the first clear identification of such an element (neptunium) was made. Between 1940 and 1961 more than 80 isotopes of 10 more transuranium elements were produced and characterized, and at the latter date more than 1,000 man-made radioactive species were known.

Of the various processes leading to production of radioactive species, neutron-induced fission of the heavy elements has been the most fruitful; this process was first identified in 1939. In 1940 it was discovered that fission may also occur spontaneously, disclosing a new type of radioactivity. The discoveries of 1934 had put an end to the belief that the types of radioactivity as then known were peculiar to elements of very great atomic weight, but in the 1960s it appeared that a similar belief was justified in relation to radioactive fission; for all practical purposes, as far as was known, spontaneous fission must be unobservable with any element below thorium (atomic number 90) in the periodic table. Moreover it was very probable that the ultimate limit in the direction of greater atomic numbers is set by the same process. By 1965 estimates were that, for atomic numbers greater than about 112, every hypothetical nucleus would be so unstable in terms of spontaneous fission that it would never be formed as an identifiable entity. Of the known transuranium elements, that of greatest atomic number (103) is lawrencium. (See TRANSURANUM ELEMENTS.)

The history of radioactivity divides (as has been shown) with the year 1934. In the following 20 years it was customary to accept this division, and to treat the subject formally under two

heads; it was so treated in earlier editions of *Encyclopædia Britannica*. One article (on so-called natural radioactivity) dealt with the phenomenon as exhibited by uranium, thorium, their congeners, and to a very feeble degree by a few other radioactive elements occurring in the earth's crust. The other article (on so-called artificial radioactivity) discussed the much larger number of radioactive species that had been man-made. Although there were historical reasons for this distinction, it was never justified in terms of the principles of physics.

The historical distinction between natural and artificial radioactivity is based on the relation of the lifetime of a radioactive species to the age of the earth. Each radioactive species has a characteristic lifetime (half-value period, or half-life). The half-life is defined as that period in which the rate of radioactive emission by a pure sample falls by a factor of two. In 10 half-value periods it falls by a factor of about 1,000; in 20 half-value periods by a factor of about 1,000,000, and so on indefinitely. For most practical purposes, after 20 half-value periods any radioactive source may be regarded as "dead." Among known species, half-lives range from 10^{-7} sec. to 10^{18} yr. By comparison, the age of the earth as a planet is estimated at about 5×10^9 yr. The only radioactive species with lifetimes within a factor of three of the age of the earth are the common isotopes of uranium and thorium (and two rare isotopes of potassium and lanthanum). By and large these are the species responsible for so-called natural radioactivity. Species of much shorter lifetime (most of those known) must have "died" long ago, even if they had been present in considerable amounts on earth when it was formed. To obtain knowledge of the thousand or more radioactive substances with effective lifetimes that are much less than the age of the earth, it has been necessary to produce these species in the laboratory; their natural breeding place is believed to be in the stars (see COSMOGONY: *Origin of Chemical Elements*).

It has been said by way of definition that radioactive substances emit energy spontaneously. More particularly, this energy is emitted in the form of ionizing radiations; *i.e.*, radiations that dissipate their energy in passing through matter by producing ionization (whereby gases may temporarily be put into a state of electrical conductivity) and other effects. The radiated energy is either kinetic energy of particles or quantum energy of photons; these are eventually degraded into heat. If the radioactive source is a compact portion of matter, some of the energy of its radiations is dissipated in the source itself; the source then tends to maintain a temperature higher than that of its surroundings. The emission is spontaneous in that it is uncontrollable by external agency; its rate is uninfluenced by all changes of pressure and temperature available to laboratory study. But it is not inexhaustible; there is no failure of the law of conservation of energy. For each source the rate of emission of energy continually decreases, as measured by its half-life. Over an infinite time the total amount emitted would be strictly finite.

It has also been said that radioactivity is an attribute of the individual atom (*q.v.*). More particularly, it is an attribute of the individual atomic nucleus. In radioactive matter the nuclei of the atoms emit energy spontaneously, and thereby tend to change their chemical character. Historically, the hypothesis of the spontaneous radioactive disintegration of atoms was put forward (and accepted as the only satisfactory account of the phenomenon) about eight years (1903) before the hypothesis of the nuclear structure of atoms was introduced (1911).

Many statements have been made without a full definition of terms thus far. The subject will now be followed more systematically, to justify and expand this introduction and summary. The detailed account that follows is organized according to this outline:

- I. Discovery of Radioactivity
- II. The Disintegration Hypothesis
- III. The Nature of Radioactive Radiations
- IV. Radioactive Series and Isotopes

I. DISCOVERY OF RADIOACTIVITY

The discovery of radioactivity in February 1896 was an indirect consequence of the discovery of X rays by W. C. Röntgen (see X RAYS). Production of X rays in a vacuum tube is accompanied by a strong phosphorescence of the glass, and it occurred to several investigators that ordinary substances made phosphorescent by visible light might emit a penetrating radiation similar to X rays. Following this idea, A. H. Becquerel placed a phosphorescent compound (uranium potassium sulfate) on a photographic plate enveloped in black paper. The weak photographic effect obtained was shown to arise from radiation that can penetrate sheets of matter opaque to ordinary light. Photographic action was later found for uranium metal and all its compounds tested, and had nothing to do with phosphorescence. Uranium showed equal activity whether kept in darkness or in the light. Becquerel showed that uranium radiations (like X rays) could discharge positively or negatively electrified objects. A uranium compound brought close to the charged plate of a gold-leaf electroscope caused a rapid collapse of the gold leaves.

E. Rutherford (1899) showed that the effect arose from the production of charged carriers (ions) in the gas through which the radiations pass. In an electric field the positive ions travel to the negative electrode (cathode) and vice versa to discharge the electrified body. If the gas is contained in an ionization chamber and a sufficiently strong field is applied, the ions are all swept to the electrodes before appreciable loss of their number can occur by recombination. The ionization current then reaches a steady maximum value that is not altered by a large increase in voltage. The maximum current through the gas is called the saturation current; its value is proportional to the intensity of incident radiation. Rutherford showed that ions produced in a gas by radiation from such substances as uranium are identical with those produced by X rays, and that the mechanism of conductivity of the gas is the same in both cases.

Marie Curie (1898) used the electric method to test a large number of chemical elements and their compounds for radioactive properties. Only thorium was found to show this effect to a degree comparable with that of uranium—a result independently established by G. C. Schmidt (see THORIUM; URANIUM). Mme Curie also found that the radioactivity of compounds of uranium was proportional to the amount of uranium present, independent of its combination with other substances. This led to the conclusion that radioactivity is an atomic property. With uranium-bearing minerals, however, Mme Curie found that the activity was always four or five times as great as that to be expected from their uranium content. If radioactivity were an atomic phenomenon, this could be explained only by the presence in these minerals of an unknown substance more active than uranium itself. Relying on this hypothesis, she made a chemical study of uranium minerals to try to separate this new radioactive substance. For these experiments the Austrian government generously provided a ton of the residues from the state manufactory of uranium at Joachimsthal (Jachymov), Bohemia. From these residues, which were three to five times as radioactive (weight for weight) as uranium, Mme Curie separated a far more radioactive substance which she called polonium in honour of the country of her birth. Further examination (P. Curie, M. Curie, and G. Bémont, 1898) revealed a second radioactive substance that separated with the barium in the mineral, to which the name radium (*q.v.*) was given. Through successive fractionations of the chloride, the radium was gradually concentrated until it had a specific activity (activity per unit mass) more than a million times greater than that of uranium. The atomic weight was determined (1902) as about 225, and a characteristic spark spectrum of bright lines was observed, similar to the spectra of the alkaline earths. Radium had all the characteristics of a new

chemical element; it had a definite atomic weight, a well-marked and characteristic spectrum, and distinct chemical properties. Its comparative ease of separation and great activity attracted much attention at the time. F. O. Giesel was the first to place preparations of a pure radium salt on the market. He found that the separation of radium from barium by fractional crystallization proceeded much more rapidly with the bromides than with the chlorides, and it was in the form of radium bromide that his preparations were marketed.

While these early chemical discoveries were being made in Paris, Rutherford, in Cambridge, Eng., reported the remarkable observation (1899) that, with a very thin layer of uranium oxide placed inside an ionization chamber, the ionization current (already of necessity very small) was reduced by a factor of about 20 when an aluminum foil 0.002 cm. thick was placed over the preparation. This simple observation indicated that the original discovery by Becquerel depended on only a very small fraction of the (ionizing) energy emitted by the uranium preparation (separated by thick black paper from the photographic detector); it also suggested to Rutherford that two distinct types of radiation were involved. With the assurance of youth (he was 27 years old) Rutherford proposed names for these hypothetical radiations. He called the easily absorbed energy alpha radiation, and the more penetrating type, beta radiation. This daring hypothesis, a characteristically inspired guess, was to be fully confirmed in a few years.

Rutherford had moved from Cambridge to Montreal, Que., in the autumn of 1898, and repeating with thorium compounds the experiments he had performed with uranium, he found that the ionization current was diminished when a slow stream of gas was passed over the preparation. When this gas was collected in a previously evacuated ionization chamber, an ionization current could be obtained in the chamber. When the chamber was sealed, the ionization current slowly decreased to zero, falling to half value in about one minute, to quarter value in two minutes, and so on. He concluded (1900) "thorium compounds continuously emit radioactive particles of some kind which retain their radioactive powers for several minutes." Later, in the same year, E. Dorn observed a similar "radioactive emanation" from a preparation of radium.

Rutherford and the Curies independently discovered the phenomenon of excited radioactivity. Rutherford described the effect with thorium as follows (1900): "thorium compounds under certain circumstances possess the property of producing temporary radioactivity in all solid substances in their neighbourhood. The substance made radioactive behaves . . . as if it were covered by a thin layer of radioactive substance." The Curies had described a similar effect with radium compounds a few months previously.

In 1901 Rutherford and F. Soddy began a long series of experiments on the emanation and excited radioactivity produced from thorium. Rutherford had already shown (1900) that the decay of the excited radioactivity in this case followed the same general (exponential) law as the decay of activity of the emanation, but that the half-life was about 11 hr. rather than 1 min. Rutherford and Soddy demonstrated (1902) that the emanation is a true molecular gas (and very probably "a chemically inert gas analogous in nature to the members of the argon family"); that it is not formed directly from thorium but from a substance "present in minute quantity" and which, when chemically separated from thorium, loses its radioactivity and potency as a source of the emanation exponentially with half-life of about 4 days. They showed that the excited radioactivity arises by deposition from the emanation of an "active deposit," as Rutherford had earlier postulated, and that the radiations from the active deposit comprise the previously recognized alpha and beta radiations.

Rutherford and Soddy then proceeded to study the emanation and excited radioactivity (active deposit) produced from radium. They found (1903) these two substances to be related in precisely the same way as those from thorium, but the half-lives they determined for the radium products were about 3.7 days (for the emanation) and less than 1 hr. (for the active deposit)—values widely different from those characterizing the corresponding products from thorium.

Rutherford and Soddy were not the only early investigators to consider the variation of radioactivity with time, but only they succeeded in bringing order to the findings. In 1899 Giesel had observed spontaneous increase of activity of radium preparations during the first few weeks after their purification, as well as gradual decrease in activity of preparations of polonium. These observations had been confirmed and extended by the Curies in the following year, but none of them had been able to formulate any simple law of time dependence.

In 1900 Sir William Crookes, while attempting to free uranium preparations from any thorium or similar impurity, found that the impurity fraction carried all of the (photographic) activity of the original preparation. He gave the name uranium X to the (then unidentified) substance, chemically different from uranium, which was thus shown to emit the beta radiation of the parent material. Becquerel independently observed a similar effect in the same year. In 1901 he was surprised to discover that his chemically purified uranium salts slowly regained photographic activity with the passage of time, and that samples of separated uranium X gradually lost their initial activity. In 1902 Rutherford and A. G. Grier showed that chemical purification did not appreciably diminish the intensity of the easily absorbed (alpha) radiation from uranium preparations. By contrast, preparations of uranium X emitted very little alpha radiation indeed. It could reasonably be concluded that alpha radiation was specific to uranium itself, and that beta radiation was specific to the "non-uranium type of matter uranium X." Rutherford and Soddy showed (1903) that the decay of activity of uranium X followed an exponential law, with a half-life of about 22 days, and that, as the uranium X lost its activity, the uranium from which it had been separated regained activity of equal amount. At any stage in that renewal of activity more uranium X could be separated from the uranium, thereby again removing from the original source the (newly formed) material responsible for its renewed activity. They speculated "that each type of radioactive matter when got by itself, free from the matter which produced it on the one hand and the products of its further change on the other, gives rise to homogeneous rays . . . either alpha radiation exclusively, or beta radiation exclusively."

By this stage (April 1903), then, radioactivity and its evident complexity had been fully recognized. Criteria had been suggested for distinguishing a single radioactive substance from a mixture of such substances: its time-decay of activity shall follow an exponential law; it shall emit alpha or beta radiation exclusively. However, no one had yet been able to detect diminution with time of the activity specific to uranium or thorium, the only radioactive substances known as chemical elements prior to 1896.

II. THE DISINTEGRATION HYPOTHESIS

Rutherford and Soddy gave a final definitive account of their theory of spontaneous atomic disintegration in "Radioactive Change" (*Philosophical Magazine*, May 1903). This startling hypothesis, designed to explain the manifold phenomena observed, had gradually taken shape over the previous two years. The last sentence of a short paper by Rutherford and H. T. Brooks, read before the Royal Society of Canada on May 23, 1901, had posed the problem clearly in terms of one particular case: "The radium emanation not only continues for long intervals to be a source of radiation . . . but in some ways manufactures from itself a . . . substance, which . . . becomes a source of secondary radioactivity." The important insight here is in the phrase "manufactures from itself"; there were two basic phenomena to be explained: the emission of ionizing radiations and the concomitant production of new types of matter. This point was stressed with greater insistence, and for the first time the notion of subatomic change was canvassed in print, in a paper by Rutherford and Soddy in July 1902: "The position is thus reached that radioactivity is at once an atomic phenomenon and the accompaniment of a chemical change in which new kinds of matter are produced. The two considerations force us to the conclusion that radioactivity is a manifestation of sub-atomic chemical change."

Rutherford and Soddy referred again to the problem in two papers published in September and November 1902. In the first

they wrote that the essential features of radioactivity "in all manifestations" are "the production of radioactive material" and "the dissipation of its available energy by radiation." Implicit in this statement was their assumption that the process of dissipation is never very slow by human standards. They imagined at that time that the seemingly constant activities that appeared to be specific to uranium and thorium would be found to arise from separable substances of "normal" lifetime. In the November paper the unnecessary complication of this view was recognized. "A slightly different view is at least open to consideration and is in some ways preferable. Radioactivity might be an *accompaniment* of the change. . . . On this view the non-separable activities of thorium and uranium would be caused by the primary change. . . ."

This modified view became the central feature of the definitive theory. In the paper of May 1903 Rutherford and Soddy stated categorically "it is not possible to regard radioactivity as a consequence of changes that have already taken place. The rays emitted must be an accompaniment of the change. . . . Apparent constancy [of radioactivity] is merely the expression of the slow rate of change of the radioelement. . . . Over sufficiently long periods its radioactivity must also decay according to the law of radioactive change, for otherwise it would be necessary to look upon radioactive change as involving the creation of matter."

Further brief quotation is probably the best way of summarizing this classical paper:

"The complexity of the phenomena of radioactivity is due to the existence as a general rule of several different types of matter changing at the same time into one another. . . ."

"In all cases . . . the law of radioactive change . . . may be expressed in one statement—the proportional amount of radioactive matter that changes in unit time is a constant . . . the constant . . . possesses for each type of active matter a fixed and characteristic value."

"The law of radioactive change . . . is also the law of monomolecular chemical reaction. Radioactive change, therefore, must be of such a kind as to involve one system only . . . the changing system must be the chemical atom . . . in radioactive change the chemical atom must suffer disintegration."

It was not necessary in the 1960s to affirm that the disintegration hypothesis of Rutherford and Soddy has long been accorded universal acceptance; never since its formulation has any alternative even been offered for serious consideration. But it is worthwhile to examine the last three quotations, for the logical connections among them are not as simple as might appear.

The first statement is descriptive of the physical situation as it was appreciated at the time; its content, however, is not fundamental. All that it involves of novelty is the empirical fact that new types of matter are formed in radioactive change. It is rather in the relation of the second and third quotations that the difficulty lies. The second quotation appears to state a general law, the third to exhibit a deduction from that law embodying the minimum of ancillary assumption. That this is assuredly not the case in no way discredits the disintegration hypothesis—every successful hypothesis in physics has involved an intuitive step beyond what was securely known, and the disintegration hypothesis is no exception.

What was known in this case was simply that the ionization current due to the radiations from a pure sample of radioactive material, in an arbitrary arrangement, decreases exponentially with the passage of time:

$$I = I_0 e^{-\lambda t},$$

where I is the intensity of the radiation at any time t , I_0 is the initial intensity, e is the base for natural logarithms, and λ is a constant. No progress beyond such a statement is possible unless notions of quantity and quality of the radiations are introduced. If it is assumed that quality remains constant, then the mathematical expression relates to the quantities: $n = n_0 e^{-\lambda t}$ (n is now the "number of rays passing through the ionization chamber in unit time"). But this statement leads nowhere without a further assumption. The flux of rays must be related to the processes taking place in the radioactive source if anything more is to be

said. Assume that each atom makes only one contribution to the flux of rays in an act of radioactive change. If N is the number of unchanged atoms present in the source, the flux of rays is proportional to $-\frac{dN}{dt}$. On this assumption

$$-\frac{dN}{dt} = A_0 e^{-\lambda t}$$

where A_0 is a constant; in consequence

$$N = N_0 e^{-\lambda t}$$

(if all the N_0 atoms initially present in the source eventually undergo the same change). From this last equation

$$-\frac{1}{N} \frac{dN}{dt} = \lambda \quad (1)$$

Logically, there is no shorter way from the experimental results of Rutherford and Soddy to the "law of radioactive change"—and the basic assumptions of the disintegration hypothesis, and others, have already been freely used on the way.

In the mathematical development of the law of radioactive change that has just been given (essentially as Rutherford and Soddy presented it), λ is the characteristic radioactive constant of the second quotation. It is deduced empirically from the ionization current measurements (when the logarithm of the current is plotted against time). The half-life has a simple relationship to λ : when $I = I_0/2$, then $t = \log_e 2/\lambda$. Representing the half-life by T , then $T = 0.693/\lambda$.

In equation (1), the mathematical paraphrase of the statement that the "proportional amount of radioactive matter that changes in unit time is a constant," the symbol N (representing a number of atoms) should strictly take only integral values. The equation itself embodies no such restriction, and to that extent it is unrealistic. Arguments along these lines were first made explicit by E. von Schweidler (1905). Von Schweidler interpreted equation (1), in relation to the individual (unchanged) atom in the radioactive source, by recognizing that λdt represents the probability that such an atom will in fact disintegrate in any arbitrary short interval of time dt . On this basis, $e^{-\lambda t}$ is the probability that the atom will still remain unchanged after a finite time t (reckoned from any instant at which it is known that the atom is still unchanged), and $(1 - e^{-\lambda t})$ is the probability that it will in fact have disintegrated during that time. In this interpretation the disintegration constant λ , defined empirically in relation to the large-scale behaviour of a radioactive source, is identified as a probability constant characterizing the individual atoms constituting the source. In equation (1) it will then be seen that λN does not give the unique, completely predictable disintegration rate at time t , when there are precisely N atoms left unchanged in the source (a situation that could not in any case be identified in practice), but instead gives some kind of average rate, or expectation value of that rate. Since the disintegration process is spontaneous, emission from a collection of similar atoms is random in time: in successive equal intervals the number of disintegrations (even in a source that is effectively constant during the time of observation) must vary around the expectation value according to simple probability theory. According to that theory these variations are relatively more important when the expectation value is small. These are the conclusions of Von Schweidler. They were first put to the test by K. W. F. Kohlrausch (1906) by the relatively insensitive method of balancing the ionization currents from two sources of alpha radiation against one another; they were first thoroughly investigated and confirmed by Rutherford, H. Geiger, and H. Bateman (1910) soon after Geiger's introduction of the first successful electrical counter of individual alpha rays (see NUCLEAR INSTRUMENTS).

Accepting the disintegration hypothesis, it is instructive to recognize the different connotations of the adjective "radioactive" as applied to bulk matter and to single atoms. When a chemical preparation is called radioactive, it is implied that an effectively steady (if diminishing) effect is produced over an extended time. For the individual atom radioactivity is a potential for change that

cannot be gauged by any test, and which is realized in a unique (unpredictable) act of disintegration in a moment of time. Radioactive atoms are in every particular indistinguishable from non-radioactive atoms, except at the instant of disintegration.

The statement of Rutherford and Soddy that "Apparent constancy [of radioactivity] is merely the expression of the slow rate of change of the radioelement" was not nearly so arbitrary in its context as it appears in isolation. Rutherford and Soddy had in fact concluded on very reasonable assumptions, "we obtain the number 6×10^{-10} as a maximum estimate for the proportionate amount of uranium or thorium undergoing change per year." On the basis of that estimate the half-life could not be less than 10^9 yr. for either substance. It is now known that the half-life of uranium-238 is 4.5×10^9 yr., and that of thorium-232 is about 1.4×10^{10} yr., so that the estimate was well founded.

III. THE NATURE OF RADIOACTIVE RADIATIONS

The preceding account of the disintegration hypothesis advisedly makes no specific reference to the nature of the radioactive radiations, save for the statement that to suppose that the radioactivity of uranium and thorium did not decay in time would be "to look upon radioactive change as involving the creation of matter." Thereby, Rutherford and Soddy implied that the radiations were material in character (*i.e.*, particles). Indeed, it had been known since 1899 that beta radiation was deviated in a magnetic field in the same sense as cathode rays (*q.v.*), and the measurements of the electric and magnetic deviations by Becquerel (1900) had left little doubt of the particulate nature of the radiation and the identity of the beta particles with negative electrons. Further confirmation was provided by more sophisticated experiments by W. Kaufmann in 1902. These experiments, in particular, demonstrated the very high velocities (within a few parts percent of the velocity of light) with which beta particles are emitted in some cases. However, in 1902 the situation had not been so clear-cut in respect of the alpha radiation; many investigators used the purely descriptive term "nondeviable" because of their failure to detect the deviation of alpha radiation with the magnetic fields and radioactive sources then available. It required a long series of experiments (extending over six or seven years) to settle the question of the nature of this radiation. From these experiments, as side issues, emerged the first tolerably accurate direct determination of the magnitude of the elementary electric charge, and the most convincing verification of a basic assumption of the kinetic theory of gases that has ever been achieved.

As long as alpha radiation was thought to be magnetically nondeviable, many workers regarded it as a type of easily absorbed X radiation. As late as September 1902 Rutherford and Soddy appeared to incline to this view. Describing the then recent discovery of beta radiation from thorium products, they wrote: "It has recently been found . . . that thorium compounds, in addition to a type of easily absorbed Röntgen rays . . . emit also rays of a very penetrating character deviable in the magnetic field." But by January 1903, Rutherford had entirely revised this opinion. He wrote, "I have recently been led, by a mass of indirect evidence, to the view that the α -rays are in reality charged bodies projected with great velocity." In May 1903 Rutherford and Soddy were in no further doubt: "In the light of this evidence there is every reason to suppose, not merely that the expulsion of a charged particle accompanies the change, but that this expulsion actually is the change."

The crucial evidence on which this revision of view was based was Rutherford's observation of the magnetic and electric deviation of alpha rays (February 1903). From measurements made with the simplest apparatus (a gold-leaf electroscope as detector, and a thin layer of radium bromide as alpha-ray source), he concluded that the easily absorbed radiation from such a source consists of positively charged particles, of mass comparable with that of the hydrogen or helium atom, projected with velocities of the order of one-tenth the velocity of light.

In the 1960s it seemed almost incredible that Rutherford should have been able to deduce such precise information from so crude an experiment. He had, in fact, estimated the specific charge (see

ELECTRON; Specific Charge e/m for Free Electrons) of the particles to within 20% of its accurately determined value. A few months previously (November 1902) he had remarked on the fact that the apparently inert gas helium (then recently discovered in terrestrial sources) is found on earth only in minerals that have uranium or thorium as an important constituent, and he had written, "the speculation naturally arises whether the presence of helium . . . may not be connected with their radioactivity." By May 1903 this speculation had hardened into personal conviction: helium was an end product of radioactivity; indeed, alpha particles and helium were merely active and passive phases of the same ultimate product; in fact, alpha particles were charged atoms of helium. That, it is clear from the evidence, was Rutherford's personal conviction at the time; but he was still a long way from proving it to others' satisfaction.

By 1906 stronger sources of radiation had become generally available, and Rutherford was able to examine alpha radiation under experimental conditions more precise than any previously contrived. He showed that, besides being the same from whatever source the alpha particles were obtained, the specific charge (e/m) was almost exactly one-half of that of hydrogen ions in electrolytes. Thus the particles could be singly charged particles of mass 2, doubly charged particles of mass 4 (helium), particles with three charges and mass 6; Rutherford did not consider that they could be heavier than this. Clearly, it was necessary to determine the charge e , if the mass m were to be known directly.

In 1907 Rutherford moved to Manchester, and in the following year he and Geiger determined the charge on the alpha particle experimentally through three distinct series of measurements: the rate of emission of alpha particles from a weak source; the rate of transport of charge by alpha particles from a very much stronger source; and the comparison of the radioactive strengths of these sources. The value obtained for the charge was 9.3×10^{-10} electrostatic units (esu). Determinations of the electronic (ionic) charge available for comparison ranged from 3.1×10^{-10} to 4.06×10^{-10} esu. There was an obvious temptation to conclude that the alpha particle carried three unit charges—but Rutherford suggested that the magnitude of the elementary charge should be revised to 4.65×10^{-10} esu. His intuition was later verified (the accurately measured unit charge is 4.80×10^{-10} esu), but he had still to convince his colleagues in other laboratories.

In 1909 Rutherford and J. T. Royds performed the crucial experiment. They introduced an intense source of radium emanation into a capillary tube, the walls of which were thin enough to allow alpha particles to pass through. In one arrangement the tube was fitted with a lead sheath, and was surrounded by an evacuated vessel. After some days, when the lead sheath was removed, and melted in a vacuum, it was established spectroscopically that helium gas was released from the lead. Control experiments showed that there had been no helium in the lead previously, and that the thin capillary tube was impervious to ordinary helium under considerable pressure. By this essentially simple experiment Rutherford reached his long-foreseen goal in a single step: "dead" alpha particles are atoms of helium gas. Harking back to the results of the previous year's determination of the charge carried by the alpha particle, Rutherford could assert that "live" alpha particles are fast-moving atoms of helium (mass 4) carrying two positive charges. In this way his earlier suggestion regarding the magnitude of the elementary electronic charge was also verified.

It should be recorded that Rutherford's speculation concerning the intimate connection between helium production and radioactive disintegration (1902) had been shown to be valid at a much earlier stage. In 1903 Sir William Ramsay and Soddy had observed production of helium by radium, and by radium emanation. In 1908 Sir James Dewar determined the rate of production quantitatively, and the experiment was repeated by B. B. Boltwood and Rutherford in 1911. Under steady conditions in a sealed container helium accumulates at a rate of 172 mm³ (at standard temperature and pressure) per year, per gram of radium enclosed.

Recall that Rutherford and Geiger had already (1908) determined the rate of emission of alpha particles from a known quantity of radium. When this value was combined with the determination

of the rate of (volumetric) accumulation of helium by Boltwood and Rutherford, what had effectively been achieved was a direct evaluation of the number of molecules of an ideal gas contained in unit volume at standard temperature and pressure. This constant of the kinetic theory of gases is Loschmidt's number, and the agreement between the value of the constant obtained from such experiments in radioactivity, and that deduced by earlier (less direct) methods, provided convincing support for the theory (*see ATOM; Size and Mass of Atoms*).

The earliest investigations (1899) of the penetrating power of beta radiation from uranium had shown that its intensity (estimated by ionization or photographic effect) was reduced to half value in about 0.5 mm. of aluminum or 0.15 mm. of copper, and that the law of absorption was approximately exponential. In 1900 P. Villard reported that a photographic effect could still be detected with radium preparations through 20 cm. of iron or several centimetres of lead; moreover, the radiation responsible for this effect was not deviable by a magnetic field. It appeared that a third type of radioactive radiation had been discovered. Becquerel confirmed Villard's observations, and in 1902 Rutherford showed that the radiations in question originated in the active deposit of radium and that very similar radiations were emitted by the active deposit of thorium. But he did not immediately accept the view that these very penetrating radiations were different in character from beta rays (electrons with velocities very close to the velocity of light would be effectively nondeviable magnetically). In the paper "Radioactive Change" (May 1903) there is, in a footnote, the first indication of such acceptance: "These rays have not yet been sufficiently examined to make any discussion possible of the part they play in radioactive processes." Then, for the first time, in June 1903, Rutherford referred to the very penetrating radiation by a distinctive name—the obvious designation, "gamma rays": "There are three distinct types of radiation spontaneously emitted from radioactive bodies, which may be called the α , β and γ rays The γ rays are probably like Röntgen rays" Others had made this last suggestion earlier, but it was not until the following year that Rutherford was really satisfied with it. Following an investigation by A. S. Eve (1904), he wrote: "All the experimental evidence so far obtained is now in agreement with the view that the γ rays are very penetrating Röntgen rays which have their source in the atom of the radio-active substance at the moment of expulsion of the β or cathodic particle . . . it is to be expected that Röntgen rays would be set up at the sudden starting as well as at the sudden stopping of the electron or β particle."

The conclusions that gamma rays are the same as X rays, and that in general their emission in radioactive disintegration is a secondary process associated with particle emission, have both stood the test of time, but the precise nature of the relationship suggested by Rutherford in 1904 has not. A secondary radiation related to beta radiation in very much the same way as Rutherford suggested that gamma rays were related was discovered (1927) as a very feeble accompaniment in all beta disintegration processes. This secondary radiation (bremsstrahlung) has since been the object of many investigations.

IV. RADIOACTIVE SERIES AND ISOTOPES

The idea of a series of successive radioactive disintegrations is explicit in the writings of Rutherford and Soddy quoted earlier (*e.g.*, "each type of radioactive matter when got by itself, free from the matter which produced it on the one hand and the products of its further change on the other . . ."). The working out of this idea proceeded rapidly in the years that followed. In May 1904 Rutherford gave a detailed mathematical discussion of its implications in a Bakerian lecture before the Royal Society of London. Before he submitted the lecture for publication in August 1904, much new material had been included, and more was added when he received the proofs for correction. At that stage four fragmentary disintegration series had been recognized, with uranium, thorium, radium, and actinium as effective parent bodies (actinium was identified and named in 1899 by A. Debierne), though it was clear that radium could not be the original parent of the third of these series, and unlikely that actinium could be the

initial parent of the fourth. In estimating the half-lives of uranium and thorium as greater than 10^9 yr. Rutherford and Soddy had also concluded that the half-life of radium could not be more than a few thousand years, "so that it appears certain that the radium present in a mineral has not been in existence as long as the mineral itself, but is being continually produced by radioactive change."

The ratio of the amount of radium to the amount of uranium in geologically old minerals that had lain undisturbed for very long periods was investigated by Boltwood, R. J. Strutt (later Lord Rayleigh), and H. N. McCoy in 1904–06. Their conclusion that this ratio is effectively constant has been amply confirmed. Unchanged uranium minerals more than a few million years old always have been found to contain about 3.43 parts of radium by weight to 10^7 parts of uranium. This is what would be expected if radium were a direct descendant of uranium in the disintegration series, and if none of the hypothetical intermediate products had a half-life longer than about 5×10^5 yr. In such circumstances there would be so-called radioactive equilibrium in the mineral, each of the daughter products being present in such amount that its rate of disappearance through disintegration counterbalanced its rate of production from the immediately preceding product in the series. Disintegration rates, in these circumstances, would be the same for all members of the series, and equilibrium concentrations by weight (more precisely, by number of atoms) of the members of the series would be in the same proportion as the half-lives (T).

Boltwood (1908) was first to try chemically separating the daughter products of uranium from an unchanged uranium mineral in the expectation of finding that their (alpha-particle) activities would be the same, as indicated above. He had already (1906) discovered a product (to which he later gave the name ionium), which he precipitated with thorium as oxalate salts, and which he showed to produce radium at a constant rate (in preliminary experiments over a period of 16 months). But when he carried out the quantitative separation, and compared the alpha activities of the products, he found the results to be less simple than had been foreseen. The activities of the ionium and radium fractions were essentially the same, but the activity of the uranium fraction was at least twice as great as either of the other two. Apart from this seeming anomaly, the total alpha activity of the untreated mineral agreed very closely with expectation, assuming that (in equilibrium with longer-lived products) the mineral must contain appropriate amounts of radium emanation and three other alpha-emitting substances of the active deposit. This double activity of uranium, and certain aspects of the chemical behaviour of ionium, may now be seen as the first of a series of puzzling facts that tended to confuse the understanding of radioactive disintegration series, until the matter was clarified by the introduction of the concept of isotopes by Soddy in 1913 (see ISOTOPE).

When the double activity of uranium was first discovered, there was no known theory to dispute the naive assumption that each disintegrating uranium atom emits two alpha particles simultaneously, whereas the atoms of all the other products each emit only one such particle. This assumption was put to the test by E. Marsden and T. Barratt (1911), who used the method of coincidences, employing two scintillation screens as particle detectors (as Geiger and Marsden had first done in the previous year). No time-coincident pairs of scintillations beyond chance expectation were found. The naive assumption was therefore negated, and it had to be concluded (Rutherford, 1912) that ordinary uranium "is a complex substance and must contain at least two components uranium I and uranium II which emit α rays . . . and are chemically so allied that none of the ordinary chemical methods are effective in separating them."

Recall that Boltwood had first separated ionium from uranium minerals by coprecipitation with thorium. By 1909 he had convinced himself (the same conclusion had been reached independently by B. Keetman) that no subsequent chemical treatment availed to separate these two substances, once mixed in aqueous solution. Moreover, he found that any method of separating ionium from a uranium mineral invariably separated the uranium

X as well. It seemed as if thorium, ionium, and uranium X (so different in radioactive properties) were indistinguishable in chemical behaviour. A similar situation developed for products that O. Hahn had been finding in the thorium series: he identified radiothorium in 1905, and mesothorium in 1907. Although it appeared that mesothorium was formed directly from the long-lived parent, thorium, and was the parent of radiothorium, it also seemed that radiothorium (half-life T about 2 yr.) was inseparable chemically from thorium itself. Thus in 1909 four products (distinct in origin and radioactive properties) were known that would unhesitatingly be labeled as thorium on the basis of standard qualitative chemical analysis. There were similar cases: mesothorium had proved chemically inseparable from radium, and radium D (the longest-lived of the products in the active deposit of radium) was inseparable from ordinary lead.

The challenge of these confusing results led to detailed studies of the chemical properties of radioactive substances in many laboratories in the years 1910–13. K. Fajans, G. de Hevesy, A. S. Russell, and Soddy and A. Fleck contributed notably. The outcome was the important displacement law announced independently by Russell, Fajans, and Soddy almost simultaneously in 1913. This states that the daughter product in alpha disintegration has a place in the periodic table two lower than that of the parent, and that the daughter product in beta disintegration holds a place one higher than that of the parent. It follows that if two products in the same disintegration series are to take the same place in the periodic table (that is, to have the same chemical properties) the simplest requirement is that there shall be two other products of the series intermediate between the first and the second of these chemically indistinguishable products, and that (overall) one alpha disintegration and two beta disintegrations shall intervene.

The displacement law very soon received a simple explanation. The nuclear atom model (see NUCLEUS) had been introduced by Rutherford in 1911, and the work of H. G.-J. Moseley (1914) was interpreted in terms of the quantitative theory of N. H. D. Bohr (1913) by the statement that the elements in the periodic table are arranged in order of increasing nuclear charge, the atomic number (taken from the table) and the nuclear charge number being identical. On this basis the displacement law follows immediately if the alpha particle carries a positive charge of two units, the beta particle has a negative charge of one unit, and if disintegration in both types of radioactive change involves the ejection of the disintegration particle from the nucleus itself. (By the Rutherford-Bohr theory the alpha particle, at least, could have no other origin.) Note that identification of atomic number with nuclear charge number indicates that the nuclear charge number of helium is 2. The whole picture, therefore, fits together; alpha disintegration involves emission from the nucleus of the radioactive atom of a helium nucleus (doubly charged alpha particle), leaving a daughter nucleus with mass number diminished by four units, and charge number appropriate to an element two places lower in the periodic table than its parent. Similarly, beta disintegration (at least in the context of classical radioactivity) involves emission of a negative electron from the nucleus, leaving the (integral) nuclear mass number unchanged, and charge number appropriate to an element one place higher in the periodic table than its parent.

According to the displacement law there should be two intermediate products of predictable behaviour between the two chemically inseparable members of each of the three pairs of genetically related products thorium-radiothorium, uranium X-ionium, uranium I-uranium II. Because thorium and uranium I are alpha emitters, the intermediate products belonging to the first and the third pairs should all be beta emitters; because uranium X is a beta emitter, the products between it and ionium should be one alpha emitter and one beta emitter. When the law was originally put forward as an empirical generalization the position was still uncertain for all these cases.

Progress toward clarification was first made for uranium I-uranium II. Fajans (1913) showed that the intermediate product uranium X was in fact a complex of two successive products (both beta emitters), the second very short-lived (half-life $T = 1.17$

min.) compared with the first ($T = 24.1$ days). These two products subsequently became known as uranium X_1 and uranium X_2 . Fajans' discovery effectively verified prediction in this particular case, but because of the great disparity in half-lives it was not until 1931 that it was shown by direct experiment that uranium II is in fact produced as daughter product in the disintegration of uranium X_2 (C. H. Collie). Thereafter, it was tacitly accepted that the sequence of disintegrations at the head of the uranium series is given as

though no one was then able to demonstrate the experimental production of ionium from pure uranium II. At the time no method was available for the separation of this product in the necessary amount. On the other hand, the accepted scheme satisfied the requirements of the displacement law for the chemical inseparability of uranium X_1 and ionium (the second of such pairs of products mentioned above), and its validity was not questioned.

For the third pair of chemically inseparable products (thorium and radiothorium) in 1908 it already was known that there were two intermediate products. Hahn had shown that the product he had named mesothorium in the previous year was a complex of two chemically separable successive products. In the nomenclature of the time these two products were designated mesothorium 1 ($T = 6.7$ yr.) and mesothorium 2 ($T = 6.13$ hr.). However, when mesothorium 2 was separated chemically from mesothorium 1 (as far as could then be ascertained) it took with it all the beta activity of the original preparation. For some years, therefore, until the displacement law was thoroughly verified, it was customary to refer to mesothorium 1 as a "rayless" product. Later investigators generally adopted the assumption that it was a beta emitter as the law required, but this was not verified by direct experiment until the 1960s (J. Tousset, 1960; Tousset and A. Moussa, 1961). The difficulty resides in the very low energy of the beta particles, the relatively long lifetime of the product, the rapid growth of its daughter mesothorium 2, and the unfeasibility of removing such radium contamination as the source very likely contains.

Implicit in the displacement law is the concept of isotopes. Empirically, isotopes are atomic species with chemical properties that put them in the same place in the periodic table; formally they are atomic species that differ in nuclear mass number A , though the nuclear charge number Z is the same. Because the only known disintegration process that involves a change in mass number (at least with the heavy elements) is alpha disintegration, mass numbers of the isotopes of any element represented by more than one member in any one disintegration series must differ by four units (or a multiple thereof). Thus if the mass number of uranium I is 238, that of uranium II is 234. In taking the various series together there is no such restriction. In the thorium series, thorium and radiothorium have mass numbers 232 and 228, but the thorium isotopes uranium X_1 and ionium occur in the uranium series with mass numbers 234 and 230, respectively.

A high-resolution mass-spectrometric analysis of natural uranium was first successfully performed by A. O. Nier in 1939 (see MASS SPECTROSCOPY). Three isotopes were found ($A = 238, 235, 234$); the first and last are the genetically related uranium I and uranium II. Their relative abundance (approximately 17,000:1) gave the first close estimate of the half-life of the lighter species (see Table I). The isotope of mass number 235 is the parent of the actinium series; its existence was postulated in this connection (1929) on the basis of F. W. Aston's mass analysis of uranium lead (see below). It was first detected by A. J. Dempster in 1935.

By 1914, apart from two places in the periodic table ($Z = 85, 87$), every value of Z for the heavy radioactive elements up to and including 92 had been found to be represented, in most cases by several isotopes. It also had become clear that (in addition to their stable isotopes) bismuth (83), lead (82), and thallium (81) had radioactive isotopes that belonged to the three disintegration series. It remained to identify the stable end product of each series, for there was no evidence of alpha activity in any species with $Z < 83$, or beta activity in any species with $Z < 81$.

As early as 1905 Rutherford had concluded that polonium

(radium F) was the last radioactive constituent of the active deposit of radium (thus the last member of the uranium series). Knowing the atomic weight of radium, the sequence of alpha disintegrations from radium to polonium, and assuming the identity of alpha particles and helium ions (based then on circumstantial evidence only), he deduced that the atomic weight of the stable end product, the daughter of polonium, was approximately 205. Noting that this value approaches that of lead (207.19), and that old uranium minerals invariably contain lead, he suggested that the lead in the mineral is the stable end product of the disintegration series. Rutherford made this suggestion even though it had been shown (K. A. Hofmann, 1901) that lead from uranium minerals is radioactive; by 1905 he had already given good reasons for supposing that this activity is to be ascribed to radium D, the grandparent of polonium. According to this view, the (temporary) radioactivity of uranium lead is no argument against the hypothesis that a variety of lead is a stable end product of the series; it is an (early) instance of the kind of chemical-identity situation that the displacement law and the concept of isotopes were later to clarify.

The suggestion that lead is an end product of radioactive transformation was made independently by Boltwood in 1905, substantiated by his chemical analysis showing that the amount of lead in uranium minerals increased with the sample's geological age.

With the acceptance of the displacement law it could be predicted that the end products of the uranium and thorium series were the lead isotopes of mass numbers 206 and 208, respectively. Determinations were made of the atomic weight of lead from primary uranium minerals (O. Hönigschmid, T. W. Richards, Maurice Curie), and a preliminary value was obtained by Soddy (1914) for the lead from a Japanese thorite (*q.v.*). These determinations strongly supported the predictions and were reinforced by subsequent similar determinations. However, definite identification of the end products (including the end product of the actinium series, the mass number of which then could not be predicted for lack of atomic weight data) came through the mass spectrograph. Aston found in common lead this isotopic mixture: Pb^{204} 1.5%, Pb^{206} 23.6%, Pb^{207} 22.6%, Pb^{208} 52.3%. With a thorium lead from Brevik, Nor., he found Pb^{206} 4.6%, Pb^{207} 1.3%, Pb^{208} 94.1%; with a uranium lead from Morogoro, Tanganyika (Tanzania), Pb^{206} 93.1%, Pb^{207} 6.9%. The complete absence of Pb^{208} in the latter case correlated well with the absence of thorium in the mineral; the Pb^{206} in the former correlated with the presence of uranium (as is almost universal). More significantly, the Pb^{207} in the uranium lead could not be explained as a chance admixture with ordinary lead, since Pb^{208} was absent; its only obvious correlation was with the actinium products that invariably occur with the products of the uranium-radium series in mineral deposits. It was concluded that Pb^{207} must be the end product of the actinium series; the later discovery of the uranium isotope U^{235} revealed the parent of that series.

By 1935 the three classical disintegration series had been fully delineated with the mass spectrograph. Reflecting the restriction in mass number in any one series, they are characterized as the $4n$ (thorium), $4n + 2$ (uranium), and $4n + 3$ (actinium) series; n may have appropriate integral values to specify the mass numbers of the products of each series.

In this section it has been tacit that the sequence in any radioactive series is unique; for example, that each atom of uranium-238 eventually undergoes precisely predetermined transformations to produce an atom of the stable isotope of lead Pb^{206} . This is an oversimplification: formally, the stability of a particular atom in relation to alpha or beta disintegration depends on whether its mass is less or greater than the sum of the masses of the disintegration particle and the product atom. Frequently, both types of disintegration are energetically possible. Atoms for which beta disintegration is least likely on energetic grounds are those of even atomic number Z , particularly those with mass numbers A that are also even. Most of the alpha emitters of the uranium and thorium series have even values for Z and A , and invariability of sequence is a marked feature of these two series. However, as early as 1906, evidence was found that could not easily be reconciled with the assumption of sequence invariability for the

products of the active deposit of thorium. Hahn found that two groups of alpha particles of very different ranges (8.6 cm. and 4.7 cm. in air at standard temperature and pressure) are emitted from these products in equilibrium, the disintegration rates appropriate to the two groups being approximately in the ratio 2:1. Such a ratio could not be understood in terms of an invariable sequence in which one alpha emitter was the daughter (or grand-

daughter) of the other. The situation was clarified by Marsden, C. G. Darwin, and R. H. Wilson (1912, 1913). They showed that the product thorium C ($A = 212$, $Z = 83$) breaks up in two distinct ways. In 65% of cases the thorium C atom emits a beta particle, in 35% of cases an alpha particle (of range 4.7 cm.). The daughter products subsequently produce a common granddaughter, thorium D (Pb^{208}); in the 65% mode from thorium C' by alpha disintegration, in the 35% mode from thorium C'' by beta disintegration. Formally, this behaviour of thorium C requires for its description two partial disintegration constants λ_α , λ_β specifying the (mutually exclusive) probabilities that (per unit time) the atom will disintegrate by the one mode or the other. In this case, equation (1) becomes

$$-\frac{1}{N} \frac{dN}{dt} = \lambda_\alpha + \lambda_\beta \quad (2)$$

representing the simultaneous decay of alpha and beta activities of a pure source of this product with half-life $T = \log_e 2 / (\lambda_\alpha + \lambda_\beta)$.

Radioactive branching, as the phenomenon of alternative modes of particle disintegration traditionally has been called, is now known to occur with all the radioactive isotopes of bismuth ($Z = 83$) belonging to the three classical disintegration series. Apart from thorium C, the other three species in this group, with the corresponding branching ratios (alpha mode:beta mode), are as follows: radium C ($1:5 \times 10^3$), radium E ($1:8 \times 10^5$), actinium C (370:1). With radium C and actinium C the phenomenon was recognized early (1912, 1914), but it was not until 1947 that the rare mode of alpha disintegration of radium E was detected by E. Broda and N. Feather. Meanwhile, an alpha mode of about 1% intensity had been established with actinium (M. Perey, 1939), and rare modes of beta disintegration had been found with radium A and actinium A (B. Karlik and T. Bernert, 1944). Then it was shown that actinium K, the daughter of the alpha mode of actinium, itself exhibits a rare alpha mode (E. K. Hyde and A. Ghiorso, 1953). Careful searches for possible alpha modes with meso-

thorium 2 (Hahn and O. Erbacher, 1926) and mesothorium 1 (Feather, N. Miller, and S. W. Peat, 1957) set upper limits of $1:6 \times 10^6$ and $1:5 \times 10^7$ in these cases.

One further aspect of branching is of interest: actinium K, formed from actinium by alpha disintegration, is an isotope of francium ($Z = 87$); the two daughter products of the rare beta modes of radium A and actinium A are isotopes of astatine ($Z = 85$). These are the only two elements within the range $83 < Z < 93$ that remained to be identified in 1914. The discoveries of 1939 and 1944 showed that these elements exist (albeit in minute quantities) in the radioactive deposits of earth's crust.

Figures 1-3 summarize the data discussed in this section through schematic representations of the successive disintegrations in the uranium, thorium, and actino-uranium (actinium) series, respectively. In these diagrams atomic number Z is plotted as the abscissa, and mass number A as the ordinate. Immediately below the atomic numbers are the symbols of the chemical elements to which they refer. Symbols given for the radioactive products are those derived from names assigned at the time of discovery (or within a few years thereafter). These names have been used in the discussion up to this point since its main concern has been historical; henceforward they will generally be replaced by the systematic nomenclature that gives the symbol for the chemical element (connoting the charge number of the nucleus) and the mass number concerned. Radium A (RaA), for example, is Po²¹⁸, mesothorium 1 (MsTh1) is Ra²²⁸, uranium Y (UY) is Th²³¹.

To supplement fig. 1-3, Table I gives the half-lives of the products; R_α is the mean (standard air) range of alpha particles for those products that are alpha emitters. When alpha disintegration is the less frequent mode the range is given in parentheses. In fig. 1 two symbols (UX₂, UZ) occupy the location Pa²³⁴, and in Table I there are two entries for the half-life against the corresponding product.

V. ALPHA PARTICLES AS PROJECTILES

From 1906, for about 25 years, spontaneous radioactive emission of alpha particles provided the only source of atomic projectiles of high kinetic energy for laboratory experiments. During that period experiments with such sources led to the discovery of the atomic nucleus, to the artificial transmutation of nuclei, and to the identification of the neutron.

In 1906 Rutherford first observed (on a slip of photographic plate about 1 cm. square) the slight blurring of the image of a narrow slit (through which alpha particles passed in an evacuated chamber) that resulted when a thin sheet of mica was placed over the slit. From this minute scattering effect, occurring in a path length of no more than 3×10^{-3} cm. in the mica, he concluded that "the atoms of matter must be the seat of very intense electric forces." In 1908, in Rutherford's laboratory in Manchester, Geiger examined this small-angle scattering in greater detail, showing that its main characteristics were not inconsistent with predictions drawn from the then-accepted atom model by Thomson. The observed scattering was interpreted as "multiple scattering"—

the resultant of the many small deflections of the alpha particle as it passed through successive atoms in the scattering foil. In the Thomson model the whole volume of the atom was assumed to be occupied by a uniform distribution of positive electrification, somehow carrying the mass of the atom, yet if alpha particles passed through atoms it was necessary to regard the volume occupied by this positive charge as entirely transparent. The interpretation was not in every respect convincing, but the resulting mathematical description (of the distribution of scattered alpha particles in relation to resultant angle of scattering) could be made to agree with experiment over the range of angles (say, from 0° to 15°, with gold as scattering material) within which the effect was significant.

This was the position in 1909 when Rutherford suggested to Marsden that he should investigate whether any alpha particles were "diffusely reflected" from thin metal foils. There was no valid reason to expect an affirmative result, but Marsden found that 0.005% of the alpha particles (from Po²¹⁴) were "reflected back" from the face of incidence when a narrow beam of them impinged normally on a gold foil equivalent in thickness to 2 mm. of air. This estimate of the intensity of backwards scattering was made on the assumption that the "reflection" was strictly diffuse, but on any basis of calculation the numerical result could not be accounted for by the same formal description as had been successful in describing earlier results. The intensity of the effect at large angles (though small in absolute terms) was many orders of magnitude greater than the theory of multiple scattering would allow. After considering the matter for more than a year Rutherford concluded that large-angle scattering could be understood only on the assumption that the backwards-scattered alpha particle effectively suffered all its deflection in an encounter with a single atom. In this case the centre of force responsible for this "single" scattering must be associated with a mass greater than that of the alpha particle; if ordinary electrostatic force were acting, the simplest requirement to achieve the necessary magnitude (in terms of the charges already supposed to exist in the atom) was that all the positive charge of the Thomson atom should be concentrated in a sphere of radius roughly $\frac{1}{10,000}$ that of the atom. Joining the two requirements, Rutherford put forward the nuclear atom model in 1911, postulating that all the mass (other than that of the atomic electrons) be concentrated in a central nucleus. On the basis of this model he worked out precise predictions regarding the distribution in angle of alpha particles that are singly scattered in passing through a thin foil; over the following two years Geiger and Marsden put these predictions to exhaustive test. Agreement between experiment and theory was startlingly good over a wide range of angle, alpha-particle velocity, and thickness of foil, and the nuclear hypothesis was verified.

In 1920 J. Chadwick used thin foils of copper, silver, and platinum to determine the absolute probability of scattering under well-defined conditions of angle and alpha-particle velocity; on the basis of Rutherford's scattering formula he deduced the magnitude of the (integral) nuclear charge numbers of these elements as 29, 47, and 78, respectively. The agreement of these numbers with the atomic numbers of the elements in question put the seal of numerical test on the whole general theory. Meanwhile the development of the expansion cloud chamber (C. T. R. Wilson, 1912, 1923) whereby tracks of individual alpha and beta particles in moist gases could be seen and photographed, provided striking visual evidence of the single scattering that Rutherford had postulated (see CLOUD CHAMBERS).

As seen in the Wilson cloud chamber (and as required by the conservation laws of classical mechanics) the large-angle scattering of an alpha particle in a close encounter with an atomic nucleus involves transfer of energy to the scattering atom. This transfer generally becomes greater as the difference in mass between target nucleus and alpha particle grows smaller. If an alpha particle were to collide directly with the nucleus of a helium atom, the atom ideally would acquire all the kinetic energy of the alpha particle, and the event would pass undetected in a cloud-chamber photograph, since the recoiling nucleus would assume all the kinetic properties of the alpha particle. It would travel the same

distance in the gas (before losing its energy through ionization) as the alpha particle would have done if it had not suffered collision. In a head-on collision with the nucleus of a hydrogen atom, an alpha particle ideally would lose only $\frac{1}{9}$ of its original energy; but the recoiling nucleus would then travel farther than the alpha particle would have done, since it has only one unit of charge rather than the two units of charge of the alpha particle (rate of loss of energy by ionization, other things being equal, being proportional to the square of the charge of the moving particle).

These considerations were first given theoretical form by Darwin in 1914; in the same year Marsden first observed the "knock-on" hydrogen nuclei (first in hydrogen gas, and then projected from thin films of paraffin wax, under alpha bombardment), determining the maximum range of the projected particles as about four times the range of the alpha particles that produced them. During the later years of World War I, Rutherford continued Marsden's investigation, and throughout 1917 paid particular attention to "an anomalous effect in nitrogen," an account of which was published with other results (*Philosophical Magazine*, June 1919). What Rutherford had observed in nitrogen—but not in helium, carbon dioxide, or oxygen—was the appearance of a few particles of range in the forwards direction about seven times greater than that of the alpha particles producing them. By simple comparative experiments he decided they were very energetic "atoms of hydrogen, or atoms of mass 2." He wrote, "If this be the case we must conclude that the nitrogen atom is disintegrated under the intense forces developed in a close collision with a swift α -particle, and that the hydrogen atom which is liberated formed a constituent part of the nitrogen nucleus."

Rutherford moved from Manchester to Cambridge in the summer of 1919, and did no further experiments on the nitrogen anomaly for some time. However, at the meeting of the British Association for the Advancement of Science in the following year, he suggested that the name "proton" should be used to denote a hydrogen nucleus with independent existence. What was to prove to be one of the primary constituent particles of the nucleus was provided with an identity (see PARTICLES, ELEMENTARY).

During 1921–24 Rutherford and Chadwick confirmed and extended the earlier observations with nitrogen, and found that, of the light elements of atomic number greater than 4 and less than 20, only carbon and oxygen did not give rise to disintegration protons when bombarded by alpha particles of Po^{214} . (It is interesting that Rutherford had chosen carbon and oxygen, along with helium, as controls in his original experiments with nitrogen in 1917.) In 1925 P. M. S. Blackett published cloud-chamber photographs showing disintegration events in nitrogen gas. From these photographs it became clear that the alpha particle was captured in the process of transmutation, and that no significant momentum was transported from the scene of collision by any particle that had failed to produce a detectable track in the chamber. On this basis the "anomalous effect in nitrogen" was described in traditional symbols as

Artificially produced nuclear transmutation of nitrogen, and of most of the elements in the periodic table up to and including potassium, became accepted fact. In order of magnitude the effect was minute: with nitrogen, about one disintegration per 10^5 alpha particles of Po^{214} completely absorbed in the gas; with potassium, at least ten times smaller—at the limit of confident detection with equipment then available.

Identification of the neutron, a third fundamental advance made through using alpha particles as projectiles, was merely an episode (albeit most important) in the study of artificial transmutation. By 1930 it had been found (W. Bothe and H. Becker) that penetrating gamma rays, as well as protons, are produced by alpha bombardment of boron, magnesium, and aluminum. These observations helped explain an otherwise perplexing result obtained the previous year: Rutherford and Chadwick found that the energies of protons produced in aluminum by alpha particles of well-determined energy were not themselves well determined. In the absence of other radiation it would have been concluded that the

balance of energy in the disintegration was an indeterminate quantity. With the discovery of gamma rays it was possible to suppose (as later confirmed by more sophisticated experiments) that, when a proton of less than the maximum energy is emitted, energy balance is subsequently restored by emission of a quantum of electromagnetic radiation. However Bothe and Becker also found gamma radiation with beryllium and lithium under alpha bombardment, and these elements did not appear to give rise to protons. Indeed, the gamma radiation with beryllium was considerably more intense than with any other element investigated. Early in 1932 Irène Curie and F. Joliot observed the surprising result that the penetrating radiation from beryllium, in passing through hydrogenous materials, projected protons with energies up to 4 Mev by some process that could only be of the nature of an elastic collision. Theoretically this was not inconceivable for gamma radiation, but their effort to interpret their results in this way involved serious difficulties regarding both the quantum energy (55 Mev) and the intensity (of the order of one quantum per alpha particle incident on the beryllium) of the hypothetical radiation.

In February 1932 Chadwick showed that the beryllium radiation produced recoil particles not only in hydrogen, but in all light elements, by elastic collision. By determining the maximum transfer of energy in a number of cases, he was able to show that the hypothesis of a quantum radiation was untenable, and that the radiation "particle" should have a mass very much the same as that of the proton. Because the radiation was highly penetrating, the constituent particles clearly were devoid of charge; Chadwick concluded that the particles were neutrons. The idea of a neutron (mass number 1 and charge number 0) as a constituent particle of nuclear structure had been suggested by Rutherford in a Bakerian lecture in 1920.

Identification of the neutron n^1 having been accepted, the primary disintegration process in alpha bombardment of beryllium was written

Subsequent investigation showed that the kinetic energies of neutrons produced by bombarding beryllium with alpha particles of a definite energy are not all the same; that, as in proton disintegration, gamma-ray emission is necessary if the balance of energy is to be constant. Later appraisal of the experiments of Bothe and Becker made it clear (considering the methods of detection employed) that what they observed in 1930 was predominantly the balancing gamma radiation, as they had supposed. Penetrating radiation observed when beryllium is bombarded with alpha particles is a mixture of gamma rays and neutrons.

VI. MAN-MADE RADIOACTIVITY

When interpretation of the "anomalous effect in nitrogen" was essentially complete in 1925, the species O^{17} (assumed to arise in nuclear transmutation of nitrogen) was unknown as a stable entity. In 1929 W. F. Giaque and H. L. Johnston postulated that this species occurs in small concentration in the oxygen of the air (along with O^{18}). They observed that certain faint bands in the absorption spectrum of atmospheric oxygen could most reasonably be explained in terms of the heavier isotopes, and estimated the concentration of O^{17} as about 0.01% of the total oxygen. In 1932 Aston observed the lines due to the molecular ions ($\text{O}^{16}\text{O}^{17}$)⁺ and ($\text{O}^{16}\text{O}^{18}$)⁺ in a mass spectrograph; determination of relative intensities by Nier (1950) gave O^{17} as 0.0374% of the total. The hypothetical transmutation product (O^{17}) of the alpha particle-proton (α, p) reaction in N^{14} was seen to be a stable species.

Even before 1929 it had been possible to adopt a similar conclusion concerning every other α, p transmutation process then observed. This conclusion was inevitable for products from the "pure" target elements fluorine, sodium, aluminum, and phosphorus. From the "mixed" elements boron, neon, magnesium, silicon, sulfur, chlorine, argon, and potassium, by a plausible assumption regarding the isotope involved in the transmutation, it could be assumed that the product species was likewise stable.

In the early 1920s, when details of the transmutation process were not yet clear, two experiments in Rutherford's laboratory (by N. Ahmad and A. G. Shenstone) dealt with the possibility that the product nucleus might not be stable. In association with the primary transmutation, no significant emission of heavy charged particles (protons or alpha particles) was observed within the first minute or two after intense alpha bombardment of nitrogen, nor within the first few ten-thousandths of a second after similar bombardment of aluminum. No systematic attempt seems to have been made to look for beta-particle emission. It was not entirely a question of lack of facilities; the cloud chamber, which Blackett was to use in 1925 to study artificial transmutation in nitrogen, could have been used even more simply to detect any electrons emitted from the products of alpha bombardment. But not until the neutron had been discovered (1932) was the stability of products of artificial transmutation again seriously discussed in Rutherford's laboratory. Then it was realized by Chadwick (1933) that the fact that a single nucleus (*e.g.*, F^{19} or Al^{27}) might emit either a proton or a neutron (on capture of an alpha particle) raised a serious problem concerning the stability of one or the other of the nuclei that are alternative products of the transmutation. Arguing from known regularities in mass and charge numbers (A and Z) of stable nuclei, Chadwick and Feather independently pointed out that if neutrons were obtained on alpha bombardment from a target species for which $A < 2Z + 1$, then the product nucleus would not satisfy one of the normal conditions for stability ($A \geq 2Z$). B^{10} (from which positron-active N^{13} was later obtained in this way) was recognized as one such target species, and Chadwick suggested (1933) that in some cases the product might pass to stability through K-electron capture (*see below*). That year in Chicago, W. D. Harkins, D. M. Gans, and H. W. Newson, having evidence that N^{16} results from neutron irradiation of fluorine, suggested that this species might transform into the stable O^{16} by emitting a negative electron. These speculations, however, were unconvincing and man-made radioactivity continued to await empirical recognition.

Man-made radioactivity was discovered by Irène Curie and Joliot in 1934. In the previous year (with a cloud chamber operated in a magnetic field as detector) they had observed emission of positive and negative electrons from target materials bombarded by alpha particles from Po^{210} . First they were inclined to think that the positrons they observed with aluminum and boron were emitted along with neutrons known to originate in alpha-induced transformations of these elements. (Arguing from assumptions later shown to be invalid, Bothe had suggested [1931] that negative electrons might be emitted along with the protons produced from boron under alpha bombardment.) Later they found that the positron activity of the target was much lower in earlier stages of irradiation than at the end, and that the activity persisted (in steadily decreasing degree) for some time after the alpha source was removed. In that way, the nature of the phenomenon became apparent.

Curie and Joliot showed that the positron-active substance produced from boron had the chemical properties of nitrogen, and that it decayed exponentially (half-life about 14 min.); similarly, the positron-active substance from aluminum had the chemical properties of phosphorus, and a half-life of $3\frac{1}{2}$ min. Finally they identified a negative-electron-active substance from magnesium, with a half-life of $2\frac{1}{2}$ min., which they concluded to be an isotope of aluminum. The conclusions can be stated more precisely

Note that the final products of radioactive decay (C^{13} , Si^{28} , Si^{28}) are all stable.

Recall that two of the first three examples of man-made radioactive species in 1934 were positron active. The positive electron had been identified only two years earlier by C. D. Anderson as a component of cosmic rays (*q.v.*) at sea level. Anderson, and

Chadwick, Blackett, and G. P. S. Occhialini (1933, 1934) independently observed positron production in the laboratory when high-energy gamma radiation was absorbed in matter. Anderson and his colleagues showed that positrons are also produced (much more rarely) as a result of the close collisions of negative electrons with nuclei. In all these cases it appeared that positive and negative electrons (of comparable energy) were produced in pairs.

These findings fitted remarkably with P. A. M. Dirac's (1928) relativistic wave-mechanical theory of the electron (*see QUANTUM MECHANICS: Dirac Electron*). This theory had considerable success in explaining the spin properties of the electron without extraneous assumptions, but could not avoid the concept of negative energy states. Serious consideration had to be given to the physical interpretation of these states. As long as a vacancy in a state of negative energy existed in any region occupied by matter, an ordinary negative electron in a state of positive energy should "fall" (in energy) into the vacancy, losing kinetic energy (and positive mass) by radiation. On this basis Dirac assumed that normally all states of negative energy must be "fully occupied"—and he showed that such a system of "completely filled" states would be unobservable. Next, physical meaning was given to the reverse transition (from a stable to an unstable configuration) in which an electron from a negative energy state is raised through absorption of energy to a state of positive energy. Assuming all the other negative energy states to be occupied, Dirac showed that this occurrence would be observed as the creation of two electrons of opposite charge, but both of positive kinetic energy. The positive electron (positron) was indeed discovered in circumstances in which the production, not of individual positrons, but of positron-electron pairs was involved.

By contrast, spontaneous emission of positrons from nuclei in beta disintegration first appeared to be a process of "creation" of a different character. However, G. C. Wick noted (1934) no necessity for this crudely empirical view. In terms of Dirac's theory the process consists in the capture (by the nucleus) of a negative electron from a state of negative energy. When the process is complete, all that is observable is the vacancy ("hole") in the otherwise fully occupied continuum of negative energy states—which "hole" is the free positron. The process involves the expenditure of energy overall, but the energy is available in the (unstable) nucleus from the beginning. Before discovery of the positron G. Gamow (1931) suggested that some atomic species might be unstable (and so be recorded as "missing" in a list of stable isotopes), suffering spontaneous transformation through nuclear capture of an extranuclear electron (probably from the K-electron shell). The suggestions of Gamow and Wick are basically the same (H. Yukawa and S. Sakata, 1935), though different amounts of "ionization" energy are involved. K-electron capture was not recognized experimentally for another seven years.

Once some of the products of transmutation under alpha bombardment were found to be radioactive, similar results were produced with other projectiles: high-energy protons and deuterons, and neutrons. The original observations, all within a period of a few weeks, were by J. D. Cockcroft, C. W. Gilbert, and E. T. S. Walton (protons); C. C. Lauritsen, H. R. Crane, and W. W. Harper (deuterons); and E. Fermi (neutrons). Before the end of 1934 many others had contributed. By the end of 1935 about 100 man-made radioactive species were known.

The first example of transmutation by gamma rays (from thorium active deposit) was observed by Chadwick and M. Goldhaber in 1934. In 1937 Bothe and W. Gentner made many substances radioactive by irradiation with the gamma rays of 17-Mev quantum energy from lithium under proton bombardment. Electron accelerators (the betatron of D. W. Kerst [1940] was first to operate successfully) provided more intense sources of high-energy quantum radiation, and greatly increased the flexibility of this method in studying nuclear transformations (*see ACCELERATORS, PARTICLE*).

In the first experimental recognition of spontaneous transformation by extranuclear electron capture (1938), L. W. Alvarez showed that Ga^{67} (formed by bombarding zinc with protons, deu-

terons, or alpha particles) preponderantly emitted a quantum radiation with all the properties of the characteristic K-shell X rays of zinc. Since there is a difference of 1 in the atomic numbers of zinc (30) and gallium (31), and since no positrons or protons appeared to be emitted, Alvarez concluded that transformation by K-electron capture produced the effects. This conclusion received strong support from the discovery of similar effects with many other man-made species, and within a year or two, transformation by orbital-electron capture was accepted as a well-authenticated mode of radioactive decay.

By far the largest single extension of knowledge of man-made radioactive species followed the discovery of neutron-induced fission of uranium by Hahn and F. Strassmann in 1939. By the 1960s considerably more than 200 beta-active species of atomic number between 30 and 63 had been identified among the products of this reaction alone. Since 1945 atomic reactors have produced neutrons of total intensity enormously greater than that of any source of charged high-energy particles, and it is of academic interest only that uranium fission may be brought about by proton and deuteron bombardment, as also by irradiation with gamma rays, in each case at energies less than 10 Mev. But the more recent use of charged particles of very high energy (100 Mev and more) for bombardment has opened a new field of investigation. The distribution of fission products from uranium is quite different with very high-energy charged particles than with neutrons of low or moderate energy; at sufficiently high energies (as I. Perlman, D. H. Templeton, and J. J. Howland first showed in 1947) ordinary stable elements from bismuth ($Z = 83$) to tantalum ($Z = 73$) undergo fission, producing radioactive species in great variety. At these very high energies, spallation (G. T. Seaborg and Perlman, 1947), in which lighter atomic particles are ejected under bombardment, yields radioactive products not produced in fission (see ATOMIC ENERGY; NUCLEAR ENGINEERING).

Since 1940 man-made radioactive species with atomic numbers higher than that of uranium ($Z = 92$) have been produced and studied in detail. By 1958, 88 such species were listed, together with another 143 species with atomic numbers from 81 to 92, many of them formed from transuranium parents by normal disintegration. As early as June 1934 Fermi and his collaborators had obtained negative-electron activities by irradiating uranium and thorium with neutrons. As with similar results with many other elements (from the lightest to the heaviest), these activities were ascribed to new isotopes of the elements irradiated; thus the daughter product in the case of the uranium activity was posited as an isotope of the hitherto unknown element 93. However, not until 1940 was Fermi's hypothetical daughter product identified as neptunium-239, the first recognized isotope of a transuranium element (E. M. McMillan and P. H. Abelson). In 1941 the alpha particles of plutonium-239 ($Z = 94$) were detected for the first time in an "old" preparation of Np^{239} ; in that way one small portion of the disintegration scheme of the new elements was in principle determined. The relevant production and disintegration processes may be represented

The daughter of Pu^{239} is naturally occurring actino-uranium, parent of the actinium series; thus all of this "natural" series may be said to be produced from uranium under neutron irradiation.

After 1945, Pu^{239} became available in considerable quantity as a possible target material for further irradiation, and techniques of producing multiply charged heavy ions and accelerating them to high energies developed. In that way it became possible to produce isotopes of elements beyond plutonium in the periodic table. Their discovery greatly widened application of the concept of the disintegration series. From experimental data of classical radioactivity, three such series had been identified, with parent species Th^{232} , U^{238} , and U^{235} , and as stable end products three isotopes of lead, Pb^{208} , Pb^{206} , and Pb^{207} , respectively. It is now clear that each series is part of an extensive system of interconnecting collateral decay chains (the species Fr^{254} , for example,

produces U^{238} through four successive alpha disintegrations). A fourth series has come to light (of mass type $4n + 1$, with Bi^{209} as its end product) that is not represented in earth's crust because its longest-lived member (Np^{237}) has a half-life of no more than 2.2×10^6 yr.

Disintegration series for the heaviest elements are most obviously regarded as sequences of alpha disintegrations, interrupted from time to time by single beta disintegrations, or by pairs of beta disintegrations. Among the radioactive products of fission, a different type of series exclusively with beta disintegrations is found in abundance. This difference is simply understood. Radioactive disintegration generally involves the transformation of an unstable species to a more stable species. Among the stable species the ratio A/Z generally increases regularly from a value 2.00 at $A = 40$ to 2.54 at $A = 208$ (and it remains almost constant about this value for the most stable species $82 < Z < 102$). When $A/Z > 2$, alpha disintegration has the effect of increasing this parameter slightly; negative beta disintegration always has the effect of reducing it more significantly. Over a range of Z within which the value of A/Z for the most stable species changes very little, therefore, many alpha disintegrations are possible in sequence before the overall trend from stability requires compensatory beta disintegration. On the other hand, since primary fragments in fission have values of A/Z very close to that appropriate to the fissioning nucleus, they are necessarily very far from stability in relation to the mass (or charge) with which they are formed. For most of these fragments (A/Z being considerably greater than the stability value for the relevant A) a sequence of several negative beta disintegrations has to occur before stability is reached. In view of these considerations it is not surprising that there has been no report of the production of any positron-active species in the low-energy fission of heavy elements.

Since the first observation of so-called stars (see COSMIC RAYS: *Methods of Detection*) in photographic emulsions by M. Blau and H. Wambacher (1937) it has been evident that nuclear transmutations of great complexity may be produced by the high-energy particles of cosmic radiation: neutrons, protons, heavier nuclei in much smaller numbers; also mesons, and other particles of transient existence. Long before all these particles had been identified, certain features of the transmutations had been studied in some detail. It would have been very surprising if the end products had been stable nuclei in every instance, and as early as 1948 the observation of characteristic "hammer" tracks (C. Franzinetti and R. M. Payne) was taken as evidence for the production of the beta-active Li^8 in certain events. It can now be assumed that there is nothing unusual in this particular case, though recognition is especially easy when the characteristic breakup of Be^8 into two alpha particles marks the occurrence:

and there can be little doubt that many "artificially" radioactive species are continually being formed "naturally" in minute amounts in the atmosphere and in the outer layers of earth's crust by the penetrating radiation from outer space. Indeed, maintenance of an effectively steady concentration of beta-active C^{14} (combined as carbon dioxide) in the atmosphere by the action of low-energy cosmic-ray neutrons on nitrogen is well established (E. C. Anderson and W. F. Libby, 1951). It is the basis of one method of estimating the age of archaeological materials (see RADIOCARBON DATING; GEOCHRONOLOGY). The transmutation reaction in this case is

Thus the distinction between natural and artificial radioactivity has become completely blurred.

VII. CONCENTRATION AND CHEMICAL IDENTIFICATION OF RADIOACTIVE PRODUCTS

Radioactive products almost invariably are found in minute concentration, and must be separated from other material to allow

careful study. Early studies were complicated by chemically impure radioactive parent materials containing numerous daughter products. Later work done by irradiating pure elementary substances with particles of a single kind simplified the situation. When full-scale investigation of fission products began, chemical complications increased.

In irradiating pure elements, products may be obtained that are isotopes of the target material, as well as those that are not. Of the two, the isotopes are the most difficult to concentrate. If the radioactive product is not an isotope of the target element, the safest procedure is to dissolve the irradiated material, add a small quantity of a so-called carrier substance containing the natural element with which the product is isotopic, and separate the active isotope with it (*e.g.*, by precipitation). Addition of the carrier guards against the likelihood that the original concentration of the transmutation product is so small that its chemical behaviour would be atypical on that account alone. When the mass of the target material is of the order of grams, it is very rarely necessary to add more than a milligram of carrier for successful separation.

Sometimes a transmutation product that is not isotopic with the target element may be separated by older methods without a carrier. For example, in 1935 M. Haissinsky separated pure Cu^{64} (produced by neutron bombardment of zinc) by electrochemical deposition on lead; as early as 1902 W. Marckwald had obtained polonium on bismuth by this method. J. Steigman (1938) separated Cu^{64} from zinc by electrolysis; F. von Lerch had already made electrolytic separations of the active isotopes of lead and bismuth from the active deposit of thorium in 1903. D. C. Graham and Seaborg (1938) used the partition between ether and 6N hydrochloric acid to separate pure Ga^{67} from irradiated zinc, as well as Mn^{54} and Co^{57} from irradiated iron; the method was used by Crookes to separate Th^{234} from uranium in 1900. Crookes found that, if uranyl nitrate is dissolved in ether, an aqueous layer separates (derived from the water of crystallization of the salt) in which the Th^{234} is concentrated. E. Segrè showed that the Na^{22} (formed from magnesium by deuteron bombardment) could be dissolved out of the hydroxide quantitatively by treating it with water; as early as 1902 Rutherford and Soddy partially extracted Ra^{224} from thorium by shaking the oxide with the same solvent. Alvarez, A. C. Helmholtz, and E. Nelson (1940) obtained practically pure Cd^{107} by condensing the vapour given off by deuteron-irradiated silver that was heated to its melting point. Although the process was not understood even in its simplest aspects until 1912 (Russell, and others), the volatilization of the active deposit of radium was first observed in 1903 by F. C. Gates; differences in volatility of the constituent products were already providing methods of separation in 1905 (W. Duane).

When the transmutation product forms an extremely insoluble compound, it may be separated by precipitation even though no carrier is added. Although the precipitate is so scant as to be invisible, it may be collected by centrifuging. In this way highly active preparations of artificially produced isotopes of titanium, scandium, yttrium, zirconium, and the rare earths have been obtained (*e.g.*, J. D. Kurbatov, M. L. Pool, and H. B. Law, 1941). The method was used successfully by C. Chamié and M. Guillot (1930) with hydroxides of the elements of the active deposit of radium. Bi^{210} and Po^{210} may be obtained carrier-free by centrifuging water in which radium emanation has been allowed to decay even though, strictly in terms of solubility, products in this case should not precipitate.

Straightforward chemical methods of separation cannot be used when the transmutation product is isotopic with the target element. L. Szilard and T. A. Chalmers (1934) were first to devise a successful (essentially chemical) method applicable in some cases. To a large amount of neutron-irradiated ethyl iodide, they added a small quantity of free iodine which (after reduction) was precipitated as silver iodide. They found that almost all the I^{128} formed in the reaction $\text{I}^{127}(\gamma, \gamma) \text{I}^{128}$ was contained in the precipitate. For this method of concentration to be successful, the transmuted target atom (a) must be removed from the molecule in which it was originally bound, and (b) must not be recaptured

into a similar molecule through isotope exchange. The first condition is satisfied in most cases of simple neutron capture. Neglecting any momentum the captured neutron may impart to the target nucleus, if a gamma-ray quantum of W Mev is emitted in capture, the nucleus (of mass number A) will recoil with energy $540 W^2/A$ ev. A recoil energy of a few electron volts is generally sufficient to free the radioactive atom from the chemical bond in the molecule, and on the average a total of about 8 Mev of energy is available for emission as gamma rays when a neutron is captured. Thus, for any possible value of A it is likely that the first condition will be satisfied. The second condition is more difficult to satisfy; it is more likely if the target material is an organic compound in which there is no ionic dissociation.

In principle the Szilard-Chalmers method of concentration also can be applied in transmutations of the class in which Z does not change (if the two conditions just mentioned are met). These conditions are generally fulfilled for radioactive chlorine, bromine, and iodine, formed in organic compounds or in the inorganic halogenates. Similarly, manganese dioxide precipitated from an irradiated permanganate is found to carry most of the radioactive manganese under certain conditions.

Radioactive halogens chemically permit many other methods of concentration when they are produced by neutron irradiation of organic halides. Erbacher and K. Philipp (1936) employed adsorption on active charcoal, and S. Roginski and N. Gopstein (1935) used both aluminum oxide and active charcoal as adsorbents. V. Majer (1937) used a trace of colloidal gold in a similar way to supply condensation nuclei for the deposition of Au^{198} atoms formed in a neutron-irradiated alkaline solution of gold chloride.

When irradiation results in a radioactive species isomeric with the isotope of the original target element, the Szilard-Chalmers method may still be used for its concentration if the necessary conditions can be met. Sometimes a product, though not isomeric with a stable isotope (of the target element or any other), is formed as two isomers, or in one form from which a second is produced by isomeric transition. Br^{80} is produced in two forms in the reaction $\text{Br}^{79}(\gamma, \gamma) \text{Br}^{80}$; the shorter-lived isomer ($T = 18$ min.) is produced from the longer-lived ($T = 4.4$ hr.) by isomeric transition. Segrè, R. S. Halford, and Seaborg (1939) modified the Szilard-Chalmers method to separate the daughter isomer from the parent. A sample of tertiary butyl bromide was prepared containing the parent isomer; subsequent extraction as hydrobromic acid carried the daughter isomer produced in the sample. D. de Vault and Libby (1940) effected the same separation by precipitating silver bromide from an ammoniacal solution containing the parent isomer as bromate; J. L. le Roux, and C. S. Lu and S. Sugden used the same precipitation from ethylene dibromide and *n*-butyl bromide. The principle has since been employed in many other separations of daughter isomers from their parents.

Under such requirements as those of the Szilard-Chalmers method (that the newly formed radioactive atom be liberated from molecular combination and be unable to return to its original state of binding) recoil of the atom on emission of the capture gamma-ray quantum may ionize the product if sufficient energy is available. (Atomic ionization energies are of the order of 5 ev to 25 ev for the loss of one electron.) If the ionized atom is not easily neutralized, it may be possible to collect the radioactive product by applying an electric field during the course of irradiation (if the target material is liquid or gaseous). Used by Fermi and associates (1935), by F. A. Paneth and J. W. Fay (1935), and by J. Govaerts (1938), the method may be applied whether or not the product is isotopic with the target element if the necessary conditions are fulfilled.

When very thin targets are employed in reactions other than those of pure neutron or proton capture, the method of recoil permits continuous collection of products during irradiation. The method was originally used for products of natural alpha disintegration by Hahn and L. Meitner (1909), following an observation by Brooks (1904). In slow-neutron-induced fission the recoil fragments have energies ranging from 40 Mev to 100 Mev. Joliot (1939) was first to use this fact, showing that radioactive

fission products could be collected on a solid surface placed some distance away from a thin layer of neutron-irradiated uranium. In the same year McMillan found what later proved to be the beta activity of Np^{239} in a thin layer of irradiated uranium from which most of the fission products had escaped by recoil. The heaviest of the transuranium elements were identified (1958, 1961) in samples containing only a few atoms, collected by recoil from heavy-ion bombardment in experiments of considerable sophistication.

Chemical separation of rare-earth elements (long a problem, and most acute for the rare-earth fraction of radioactive fission products) was virtually solved with ion-exchange resins (see ION EXCHANGE). These resins commonly are organic polymers, such as polythene, carrying functional groups that make hydrogen or hydroxyl ions easily available by ionization. In a cation-exchange resin these groups may be sulfonic or carboxylic acid groups or a phenolic hydroxide; in anion-exchange resins they may be a quaternary amine or an ethanol group. The method was introduced by G. E. Boyd, F. H. Spedding, and W. E. Cohn, and their co-workers (1947). A long column is packed with the appropriate resin; the material to be separated is shaken up for adsorption with a sample of the resin under controlled acidity, the mixture is placed at the top of the column, and a suitable eluting agent is allowed to flow slowly through. Lanthanide rare earths are separated with a cation-exchange resin; 0.25 molar citric acid (brought to pH 3.05 with ammonia) is a satisfactory eluent (G. Wilkinson and H. G. Hicks, 1947) at a rate of flow of 0.03 millilitre/cm² min. In such an arrangement the rare earths appear in the reverse sequence of atomic numbers as elution proceeds: Lu, Yb, Tm, Er, . . . (see RARE EARTHS). It was early suspected and later established that a second series of rare-earthlike elements has actinium as its first member. All known transuranium elements belong to this actinide series. The ion-exchange column enormously aided study of these elements; since about 1950 all separations of the higher transuranium elements have been made this way. Generally, tracer amounts of almost any two ionic species may be separated by ion exchange if appropriate conditions are established; by suitable increase in column size, macroscopic amounts of material may be handled with equal success.

This section has dealt chiefly with the concentration of known radioactive products of transmutation. Obviously when the species is not known, chemical and other methods of separation greatly assist in identification.

VIII. MATHEMATICAL THEORY OF SUCCESSIVE TRANSFORMATIONS

It has been shown how Rutherford and Soddy developed the law of radioactive change from experimental data. Their first-order differential equation

$$\frac{dN}{dt} = -\lambda N$$

was interpreted as giving the expectation value of the disintegration rate of a pure radioactive sample at the instant when N atoms of the original material remain unchanged; λ is the empirically determined disintegration constant of the material. Generally (though not invariably) N is a very large number; and λN quite frequently represents a high rate of disintegration, so that fluctuation effects are relatively unimportant. In view of this it should be stressed that the mathematical theory to follow considers no such fluctuations, treating a random phenomenon as if it were causally determined, and taking no account of restriction of N to integral values. This imposes a formal restriction on the relevance of the theory (in some circumstances a more sophisticated approach may be necessary), but it is entirely adequate for most experimental purposes.

Rutherford (1904) was first to formulate and solve differential equations representing successive disintegrations of specific parent substances to stable end products. A more general treatment was first given by Bateman (1910).

If $N_1, N_2, \dots, N_k, \dots, N_r$ represent numbers of atoms of the products (N_1 parent atoms . . . N_r atoms of stable end product)

of a single-chain disintegration series in a given sample at any time t , the appropriate differential equations are

$$\begin{aligned} \frac{dN_1}{dt} &= -\lambda_1 N_1 \\ \frac{dN_2}{dt} &= \lambda_1 N_1 - \lambda_2 N_2 \\ &\dots \\ \frac{dN_k}{dt} &= \lambda_{k-1} N_{k-1} - \lambda_k N_k \\ &\dots \\ \frac{dN_r}{dt} &= \lambda_{r-1} N_{r-1} \end{aligned} \quad (3)$$

where $\lambda_1, \lambda_2, \dots, \lambda_k, \dots, \lambda_{r-1}$ are disintegration constants appropriate to each product. The general solution of this set of equations may be written

$$\begin{aligned} N_1 &= {}_0N_1 e^{-\lambda_1 t} \\ 1 < k < r, N_k &= {}_0A_k + \sum_{j=1}^k {}_jA_k e^{-\lambda_j t} \\ \sum_1^r N_k &= \sum_1^r {}_0N_k \end{aligned} \quad (4)$$

Here ${}_0N_k$ is the number of atoms of the k th product present in the sample at $t = 0$; the constants ${}_jA_k$ depend on these initial values and on the magnitudes of the disintegration constants concerned.

Equations (4) may seem too complicated for easy application, but they may be considerably simplified without loss of generality. Since this spontaneous process proceeds so that the disintegration of any atom is totally uninfluenced by that of its neighbours, solution for any set of initial conditions (values of ${}_0N_k$ different from zero for all values of k from 1 to r) may be obtained by superposition of simpler solutions in which each product in turn is regarded as the only one present in the original sample. It is then sufficient to solve for the case in which only atoms of the parent species are present initially (in number ${}_0N_1$), and then apply this solution to the other products in turn (their initial amounts being specified), merely adding the resulting expressions. When only the original parent is present at $t = 0$, values of the constants ${}_jA_k$ of equations (4) are given explicitly as follows ($1 < k < r$, $0 < j < k + 1$):

$$\begin{aligned} {}_0A_k &= 0 \\ {}_jA_k &= \frac{{}_0N_1 \lambda_1 \lambda_2 \dots \lambda_{k-1}}{(\lambda_1 - \lambda_j)(\lambda_2 - \lambda_j) \dots (\lambda_{j-1} - \lambda_j)(\lambda_{j+1} - \lambda_j) \dots (\lambda_k - \lambda_j)} \end{aligned} \quad (5)$$

Consider the general solution represented by equations (4) and (5) when the parent has a half-life significantly longer than that of any of its daughters. In that case λ_1 is the smallest of the disintegration constants involved, and (if λ_j is next smallest) then at times considerably greater than $1/\lambda_1$ only one term in any of the expressions in (4) remains significantly different from zero. This is the term involving $e^{-\lambda_1 t}$; i.e., the first term in each expression. After a certain time, therefore, all the products effectively decay together, with the half-life of the parent, and the relative amounts of the products still present in the sample remain constant with time. In such case the successive products are said to be in radioactive equilibrium with the parent, under which

$$\frac{N_k}{N_1} = \frac{{}_1A_k}{{}_0N_1} = \frac{\lambda_1}{\lambda_k - \lambda_1} \left[\frac{\lambda_2}{\lambda_2 - \lambda_1} \dots \frac{\lambda_{k-1}}{\lambda_{k-1} - \lambda_1} \right] \quad (6)$$

When the disparity between the half-life of the parent and that of the next longest-lived product is very great ($\lambda_1 \ll \lambda_j$), to a very close approximation equation (6) may be written

$$\lambda_1 N_1 = \lambda_2 N_2 = \dots = \lambda_{r-1} N_{r-1} \quad (7)$$

When equation (7) applies without significant error (as in the case of an old and unaltered uranium [or thorium] mineral) the radioactive state is called secular equilibrium; when equation (6)

must be used, the equilibrium is said to be transient. Disintegration rates at any time in secular equilibrium are essentially the same for all members of the genetically related series; in transient equilibrium, according to equation (6)

$$\lambda_1 N_1 < \lambda_2 N_2 < \dots < \lambda_{r-1} N_{r-1}$$

and disintegration rates increase progressively from one product to the next throughout the series.

When Rutherford first solved equations (3) for his experimental data (1904), direct determination of disintegration rates was not a practical possibility. All that was measured was an ionization current proportional to the disintegration rate for a pure source, with an unknown constant of proportionality, and differing considerably from one pure source to another. For a given disintegration rate the ionization current would almost certainly be greater (by an order of magnitude or more) for an alpha-emitting source than for a beta emitter; such complications now generally can be avoided. However, Rutherford encountered one situation of special interest, whatever experimental techniques are available. It occurs when $r = 3$ in equations (3), and when the parent and radioactive daughter emit radiations of different types, one much more easily detectable than the other. Investigators will first tend to use the easily detectable radiation. If a source originally contains only the parent substance it may be found that the easily detectable activity decreases exponentially with time; in which case the radiation belongs to the parent, and its half-life may be determined directly. If the radiation belongs to the daughter its intensity will vary with time in proportion to $\lambda_2 N_2$ where, from equations (4) and (5)

$$N_2 = {}_0N_1 \left(\frac{\lambda_1}{\lambda_2 - \lambda_1} e^{-\lambda_1 t} + \frac{\lambda_1}{\lambda_1 - \lambda_2} e^{-\lambda_2 t} \right) \quad (8)$$

Values of λ_1 and λ_2 may be deduced from experiment, but the symmetry of the situation is such that it cannot be decided (on this evidence alone) which value refers to the parent and which to the daughter. According to equation (8) $\lambda_2 N_2$ varies with time in precisely the same manner whether the smaller of the two constants refers to the parent or to the daughter.

This discussion has been confined to single-chain disintegration series for simplicity. Series branching involves no new principles; only added complexity in mathematical formulation. The basic expression for the law of radioactive change in branching disintegration has been given as equation (2). All that is needed is appropriately to introduce an expression of this type in equations (3), and to represent disintegration side-chains separately to arrive at the set of simultaneous differential equations for the more general case.

No new mathematical approach is involved when radioactive substances are produced from stable species by controlled irradiation. Equations (3), with their solutions given in equations (4) and (5), provide a complete description of an ideal situation of this class through a simple reinterpretation of the symbolism. Description of an actual situation may then be derived by suitable superposition of partial solutions and adjustment of parameters.

The ideal situation to which equations (3), (4), and (5) immediately apply is that in which ${}_0N_1$ atoms of a single kind are placed in a uniform field of irradiation of constant intensity at time $t = 0$, and when only one type of transmutation is possible. If the transmutation gives rise to a radioactive product, N_2 in equations (3) represents the number of atoms of this product (of disintegration constant λ_2) present after irradiation duration t , and N_1 gives the number of parent atoms still unchanged. The remaining symbols N_3, N_4, \dots, N_{r-1} allow for the possibility of intermediate products before a stable end product is reached; N_r denotes the number of end-product atoms present at t .

The symbol λ_1 in the equations is interpreted in terms of flux density of bombarding radiation (in particles or quanta per unit area per unit time) and the cross section of the target nucleus for the relevant transmutation (as an area per nucleus) under the conditions of irradiation obtaining. If ϕ represents this flux density and σ this nuclear cross section, then $\phi\sigma$ gives the prob-

ability per unit time that any atom of the target species remaining unchanged will suffer transmutation. Expressed this way, the significance of $\phi\sigma$ is precisely that of a disintegration constant in a spontaneous process; the required interpretation is: $\lambda_1 = \phi\sigma$.

Values of ϕ and σ vary considerably from one practical situation to another. In nuclear reactors the flux density of slow neutrons may reach 10^{14} (or in extreme cases 10^{15})/cm² sec., and (depending on the target material) σ may have any value up to about 10^{-20} cm² per nucleus under these conditions. In fast-neutron reactions, and those produced by high-energy charged particles (generally in light nuclei) σ will more usually be 10^{-28} to 10^{-24} cm² per nucleus, but radiation flux densities tend to be smaller. A beam current of singly charged particles of 1 microampere focused on an area of 1 cm² corresponds to a mean ϕ value of 6×10^{12} /cm² sec.; however, in accelerators producing particle energies of a few hundred million electron volts, average beam currents are more likely to be of the order of 1 millimicroampere. Values of $\phi\sigma$ then range from about 10^{-6} /sec. to 10^{-18} /sec. in practical situations, and the effective half-life T_1 of the target material in such transmutation will range, accordingly, from about 1 day to 10^{10} yr. Very much more frequently than not, T_1 will be considerably longer than the total time of irradiation in laboratory experiments.

Equation (8) provides an expression that can be interpreted in relation to the production of radioactivity by controlled irradiation. With $\lambda_1 \ll \lambda_2$, $t \ll T_1$, the equation becomes

$$\lambda_2 N_2 = \phi\sigma {}_0N_1 (1 - e^{-\lambda_2 t}) \quad (9)$$

In this form it gives the activity of the directly produced radioactive product (in all but the most extreme circumstances; see above) as a function of irradiation time. According to equation (9) the activity of the first product eventually reaches a saturation value $\phi\sigma {}_0N_1$, and its atomic concentration in the target material reaches a value of $\phi\sigma/\lambda_2$. This concentration, which cannot be exceeded under the given conditions of irradiation, may also be expressed as the ratio T_2/T_1 , where T_1 is the characteristic time defined in the last paragraph, and T_2 is the half-life of the transmutation product concerned. If a target material with nuclear cross section 10^{-24} cm² for thermal neutron capture that gives rise in this way to a product of half-life 2 hr. is irradiated in a nuclear reactor at flux density 10^{12} /cm² sec., it will develop at saturation a concentration of roughly one atom in 10^8 of the product. This arbitrary example (typical of practical experience) emphasizes the magnitude of the problem of separating or concentrating the active material in the short time before it loses its activity.

IX. RADIOACTIVITY AS A PROPERTY OF THE ATOMIC NUCLEUS

It was recognized early, in the context of the nuclear atom model, that so-called natural radioactivity is essentially a property of the atom nucleus; that an alpha particle (helium nucleus) or a beta particle (negative electron) is emitted spontaneously from an intrinsically unstable nucleus. A similar interpretation was later applied to radioactivity produced in man-contrived experiments. Positron emission and orbital-electron capture (empirically unknown before 1934) were accepted from the outset as nuclear processes.

In 1965 there were about 270 species listed as stable isotopes. To be so listed, a species had to have been detected in mass analysis of terrestrial material, and could not have been shown to be radioactive. Improved sensitivity of mass spectrometers may tend to add to the list by revealing species present in samples in previously undetectable amount; but improvements in the sensitivity of particle counters may show feeble radioactivity of species thought to be stable. On the basis of present knowledge such improvements are most likely to reduce the number of species accepted as stable. In a two-dimensional diagram with mass numbers represented along one side of a rectangular grid and charge numbers along the other, each grid point represents a possible nuclear species. Points representing accepted stable species form a well-defined band across such a diagram, and the much more nu-

merous points representing man-made radioactive species encompass this band on either side and fill in the gaps in its structure; there were (1965) very few unfilled points within the band of conceivable stability.

Nuclear stability can be considered in relation to heavy-particle (e.g., alpha-particle) emission, and in relation to electron emission (or capture). In some respects the second is more fundamental, yielding a very simple generalization that has no counterpart in the case of heavy particles. This generalization states that it is overwhelmingly unlikely that two isobaric species (so-called because they have the same mass number) can both be stable if their nuclear charge numbers differ only by one unit.

Consider two such neighbouring isobars (A, Z) and ($A, Z + 1$); it is a truism that the exact masses of the two neutral atoms cannot be precisely the same. If the neutral atom (A, Z) has the greater mass, then mass-energy is available for emission of a negative electron from the nucleus. For, if this electron were taken up in the extranuclear electron cloud, it would produce the neutral atom ($A, Z + 1$). If the neutral atom ($A, Z + 1$) has the greater mass, then capture of one of its outer electrons by the nucleus is energetically possible, producing the neutral atom (A, Z). Either case rests on the assumption that the nuclear process is completely described; but, apart from this, the statement is precise. One or the other of a pair of neighbouring isobars is intrinsically unstable in relation to an electron-involved process (either emission or capture of a negative electron). It was satisfactory to find that in the 1960s there remained no more than a single case of neighbouring isobars in the accepted list of stable species.

The concept of stability against electron processes can be applied to nuclei for which Z exceeds 83 in precisely the same way as it has just been applied to nuclei of smaller Z . For $Z > 83$ it is currently supposed that all nuclei are intrinsically unstable in relation to alpha disintegration (see below), but the problem of beta stability is a separate issue. By extending the argument of the last paragraph very slightly it may be concluded that all species of any given mass number A (and $Z > 83$) are intrinsically unstable in a single sense (all capture-active or all negative-electron-active, except the end product having $Z = 0$ or $Z = A$, as the case may be), or else that at least one such species is stable against both types of (electron-involved) transformation. Of these alternatives, only the second conclusion makes sense physically; the other implies a degree of discontinuity in the general properties of nuclei at $Z = 83$ that is quite contrary to experience. Precise measurements of disintegration energies for the 200 or more species known to belong to the disintegration series of the four mass types discussed in section VI permit calculation (by the method of closed decay cycles) of the energies available for electron-involved disintegration in cases in which such disintegrations have not hitherto been observed. In this way it has been shown that beta-stable species do indeed occur with $Z > 83$ (L. A. Turner, 1940), as the general argument would indicate. A list of these species is given in Table II.

Table II.—Beta-stable Species with $Z > 83$

Z	A
84	210, 211, 212, 213, 214, 216
85	215(?)
86	214(?), 215(?), 216, 217, 218, 220, 222
87	219
88	220, 221, 222, 223, 224, 226

99	253
100	252, 254, 255, 256

The table shows that the distribution in A and Z for these alpha-unstable but beta-stable species has the same character as that for species normally regarded as both alpha- and beta-stable in the range of smaller Z (< 84). In this connection the main feature to be noted is the different incidence of odd and even values of

A and Z in either distribution. No odd value of A is given with confidence more than once in Table II; no value of Z is associated with more than two odd values of A ; no odd value of Z is associated with any even value of A . These rules apply (with negligible exceptions) throughout the whole range of Z as well as to the restricted range covered by the table. This serves to justify the earlier statement that in some respects the question of beta stability is more fundamental than that of alpha stability.

For all species (with $Z > 82$) identified as alpha emitters, disintegration energy empirically exceeds 4 Mev. Beta emitters, on the other hand, include radioactive species with disintegration energy as low as a few thousand electron volts. Note that within any small range of Z , the half-life of an alpha emitter increases very rapidly indeed as disintegration energy decreases. In summary, absence of experimentally detectable beta radiation is a relatively trustworthy indication of a product's absolute beta stability; the absence of detectable alpha radiation would be a much less reliable indication of absolute alpha stability in comparable circumstances. If the product were of large Z , all that could reasonably be deduced from such a negative experiment might be that the energy available for alpha disintegration must be less than 4 Mev in that case. The conclusion from known facts is that the energy available for alpha disintegration decreases abruptly as Z decreases below 83; but it would be rash to conclude that all species of smaller Z are alpha-stable in the absolute sense.

In current theory the nuclear constituent-particles (nucleons) are protons and neutrons. A nucleus of mass number A and charge number Z is assumed to contain Z protons and $A - Z$ neutrons. On this basis an alpha particle comprises two protons and two neutrons; this system is relatively the most tightly bound (stable) of all possible nucleon combinations. In terms of available energy this is the reason that alpha-particle emission (rather than emission of protons or any other charged composite particles) occurs at all significantly in nature.

The energy available for alpha emission can be expressed in terms of the energies binding nucleons. It is supposed that two protons and two neutrons are removed one by one (it does not matter in what order) from the original nucleus. At each removal the binding energy of the appropriate nucleon must be supplied from outside. When the four particles have been removed in this way let them combine to form an alpha particle. In this process the total energy binding the alpha particle is released. The energy Q_α available for alpha disintegration of the original nucleus is the excess of this liberated energy over that supplied from outside. Let B represent binding energy, p proton, and n neutron; then

$$\begin{aligned}
 Q_\alpha(A, Z) &= B(4, 2) - B_p(A, Z) - B_p(A - 1, Z - 1) - \\
 &\quad B_n(A - 2, Z - 2) - B_n(A - 3, Z - 2) \\
 &= B(4, 2) - B_p(A, Z) - B_n(A - 1, Z) - \\
 &\quad B_p(A - 2, Z) - B_p(A - 3, Z - 1)
 \end{aligned}$$

Two variants (not shown) represent the other possible sequences of removal of the four particles concerned.

Recall that it has been concluded from experimental data that energy available for alpha disintegration decreases abruptly as Z decreases below 83. From the analysis just given, this implies that the binding energies of the last added protons or neutrons (or both) must increase abruptly as Z decreases through this value. This is one of the many generalizations from experimental results which are regularized in the shell model of the nucleus (M. G. Mayer, J. H. D. Jensen, *et al.*, 1949). According to that model (see NUCLEUS: *Nuclear Structure and Nuclear Forces*), as nuclei are built up by successive addition of nucleons, the binding energy of the last added particle varies in a periodic manner. There is an odd-even variation whereby the binding energy is less, when an odd-numbered particle is added, than when the next (even-numbered) nucleon of the same kind is added. (This consideration is basic for understanding the systematic characteristics of beta-stable nuclei discussed earlier.) There is also a variation with longer periods, within each of which the binding energy rises progressively to a peak value at the end of the period. These periods end at the proton (or neutron) numbers 2, 8, 20, 50, 82, and

126. On the basis of this model, the cutoff in relation to alpha-disintegration energy for $Z < 83$ is particularly sharp because two of these so-called magic numbers are involved in this range of Z ; the stable end product of the thorium series is the doubly magic species Pb^{208} ($Z = 82$, $A - Z = 126$). Pb^{208} is the daughter of alpha-active Po^{212} , and it is consistent with the shell model that the value of Q_α in this case is greater than that for any other isotope of polonium (84) or bismuth (83). The entries in Table III substantiate this, and also give alpha-disintegration energies of the isotopes of astatine (85) for comparison.

Table III. Values of Q_α (Mev) for the Isotopes of Astatine, Polonium, and Bismuth

$Z \backslash N$	126	127	128	129	130	131	132	133	134
85	5.98		9.4	8.95	8.15	7.94	7.18	6.75	6.39
84	5.40	7.39	8.95	8.51	7.83	7.50	6.90	6.66	6.11
83	3.2	5.04	6.75	6.21	5.97	5.61			

Table III shows proton number Z along one axis, and neutron number N ($= A - Z$) along the other. Variation of Q_α with N , for constant Z , shows a pronounced maximum at $N = 128$ for each Z value; for N constant, the increase in Q_α between $Z = 83$ and $Z = 84$ is in general greater by a factor of about 5 than it is between $Z = 84$ and $Z = 85$. (For higher Z values not shown in Table III the rate of Q_α increase with Z , at constant N , continues quite small.) Thus the phenomenon of alpha disintegration emerges suddenly, being empirically unobservable ($Q_\alpha < 4$ Mev) when $Z < 83$ and $N < 127$, and highly energetic when $Z > 83$ and $N > 127$.

The entry $Q_\alpha = 3.2$ (for $Z = 83$, $N = 126$) in Table III refers to the nominally stable species Bi^{209} ; it reflects the repeated report (e.g., W. Porschen and W. Riezler, 1956) of detecting very feeble alpha activity with ordinary bismuth. The estimated half-life is 2×10^{17} yr., and the observed disintegration energy is what might be expected on the basis of the shell model. The observation seems valid, though avoidance of background effects at this level of activity is almost impossible; it emphasizes the need for the caution already expressed, that the absolute and empirical limits of alpha stability (on the A/Z diagram) are far from the same. After 1956 definite evidence was found for weak alpha activity with hafnium and platinum as well. Experiments with sources of enriched isotopes have made it possible to attribute these activities to the rare isotopes Hf^{174} and Pt^{190} (0.18% and 0.012%, respectively, of the normal element), and to determine the respective disintegration energies and half-lives as 2.56 Mev and 3.18×10^{16} yr. and 7×10^{11} yr. (R. D. Macfarlane and T. P. Kohman, 1961; K. A. Petrzhak and M. I. Yakunin, 1962).

The first alpha activity observed with an element of $Z < 83$ was that of ordinary samarium (62) (De Hevesy and M. Pahl, 1932); it was unambiguously attributed to Sm^{147} (B. Weaver, 1950) by isotope separation. The disintegration energy is 2.29 Mev, and the half-life is 1.4×10^{11} yr. (See SAMARIUM.)

Even before the isotopic attribution of its alpha activity had been settled, samarium had been recognized as unique in another respect among the "stable" elements of even Z . For all other such elements the mass spectrum of the isotopes of even A is of the same general type: a compact group of lines with no missing member. With samarium the inner line of Sm^{148} is missing. The shell model indicates that alpha activity is most likely to appear (if at all) with the medium-heavy nuclei, among those with neutron number 84 or slightly greater; for Sm^{148} $N = 84$, and for Sm^{147} $N = 85$. This conformity with prediction spurred the production of such species by man-made transmutation (S. G. Thompson, J. O. Rasmussen, and Seaborg, 1949; Rasmussen, Thompson, and Ghiorso, 1953; D. C. Dunlavy and Seaborg, 1953). In this way Sm^{148} , Eu^{147} , Gd^{148} , Gd^{149} , Gd^{150} , Tb^{149} , Tb^{151} , Dy^{152} , Dy^{153} , and Dy^{154} were shown to be alpha emitters. It was also shown that Nd^{144} (23.9% in ordinary Nd) is alpha active, with half-life the order of 10^{16} yr. (E. C. Waldron, V. A. Schultz, and Kohman, 1954; Porschen and Riezler, 1954). Alpha activity of the rare isotope Gd^{152} (0.2% in ordinary Gd) was

established (Macfarlane and Kohman) in 1961.

Table IV shows values of alpha-disintegration energies for this group of species. The same general features appear as in Table III: for constant Z , Q_α passes through a maximum as N increases (the maximum occurring when N is two units greater than the magic number, in this case 82); for constant N , Q_α increases slowly with Z (there is no magic proton number involved in this case). The empirical limit of alpha stability now occurs ($Z \sim 60$) at about $Q_\alpha = 2$ Mev, rather than at about 4 Mev as when $Z \sim 80$. All except three of the cells in Table IV represent man-made species that are unstable in terms of electron capture. In these circumstances alpha disintegration is merely a rare mode in a fairly short-lived activity, so its detection presents experimental difficulties.

Enough is known about the exact masses of nuclei, on the basis of reaction energies characteristic of transmutations with a variety of projectiles (L. A. König, J. H. E. Mattauch, and A. H. Wapstra, 1962), to predict values of Q_α with fair accuracy for a great many species. Through application of semiempirical mass laws (P. A. Seeger, 1961) these predictions may be extrapolated to all species at all likely to be produced. The chance of obtaining experimental evidence of alpha activity associated with values of N or Z just greater than the magic number 50 is extremely

Table IV.—Values of Q_α (Mev) for the Alpha-active Isotopes of Neodymium, Samarium, Europium, Gadolinium, Terbium, and Dysprosium (bracketed values represent uncertain attributions)

$N \backslash Z$	60	61	62	63	64	65	66
88					2.20		3.46
87							3.57
86					2.8	3.53	3.76

84	1.88		2.62	2.96	3.25	4.06	(4.31)

remote. In low-energy fission of heavy elements certain species are produced in small yield (as primary fission fragments) that would appear in Table IV if it were extended to smaller Z values. Predictions are that Q_α is positive for some of these species (in particular for La^{141} , Ce^{143} , Ce^{144} , Pr^{145} , Nd^{148} , and Nd^{149}). This may have some bearing on the emission of alpha particles in fission (Feather, 1964).

X. BETA DISINTEGRATION AND ELECTRON CAPTURE

Even if it had not marked discovery of man-made radioactivity and the associated process of spontaneous positron emission, 1934 would represent a turning point in the study of beta disintegration. The main features of negative beta disintegration had been laboriously learned from naturally radioactive species, the proton-neutron model of the nucleus (W. Heisenberg, 1932) had come to be accepted, and the neutrino hypothesis (see below) had been suggested by W. Pauli (1931). Remarkably, all these developments were compounded in 1934 in Fermi's coherent theoretical account of disintegration. Formulated in general terms, the theory later was used to describe positron emission and orbital-electron capture with equal success; in 1965 (some of its ambiguities having been resolved) it remained the accepted general theory of electron-involved nuclear processes.

The crucial observations prompting the theory were made largely with naturally radioactive Bi^{210} (radium E) in the 1920s. This body is particularly suitable for such experiments since it has no significant gamma radiation to complicate observation; it has a single longer-lived alpha-active daughter (Po^{210}); its half-life (5 days) is convenient for laboratory work. The daughter provided an independent monitor of disintegration rate, and a comparison unit of energy (the known kinetic energy of the alpha particles of Po^{210}).

When the experiments with Bi^{210} were planned, the main problem had already been identified. Chadwick had shown (1914) with electrical recording methods that the magnetic spectrum of electrons emitted by sources of radium active deposit (Po^{214} , Bi^{214}) consisted of a continuous distribution and a series of spectral lines. The lines had been the subject of much study through

photographic recording (e.g., Rutherford and H. R. Robinson, 1913), but the continuous spectrum had not yet been accurately observed. The total intensity of the lines was low compared with that of the continuum, and Chadwick deduced that the disintegration electrons must belong to the latter, the electrons of the lines being of secondary origin. Rutherford, Robinson, and W. F. Rawlinson (1914) independently concluded that the electrons of the line spectrum were secondary, in the sense that they obtained very similar groups of electrons by passing the gamma rays of the source through thin metal foils. The immediate problem was whether the continuous spectrum was a feature of all beta disintegrations, even the simplest; and, if so, how to reconcile this apparent variation of energy with the conservation law. A basic question was whether the continuous spectrum represented one electron per disintegrating atom, or more.

In 1924, K. G. Emeléus used the disintegration rate of the daughter Po^{210} as monitor to show that the average number of electrons detectable for each disintegration of Bi^{210} is very close to one. In 1927, E. Madgwick found the magnetic spectrum of these electrons to be continuous. In the same year C. D. Ellis and W. A. Wooster determined (in terms of the energy of the alpha particles of Po^{210}) the average energy per disintegration appearing as heat when radiations of Bi^{210} were absorbed in the metal walls of a microcalorimeter. The first two experiments showed the continuous spectrum to be characteristic of the disintegration electrons; at least these electrons did not seem to dissipate energy significantly by sharing it with other electrons through some preferential interaction within the disintegrating atom. The experiment of Ellis and Wooster showed that the heating effect corresponded to the average energy of the continuous spectrum, rather than the maximum energy, so that no other (easily absorbed) secondary radiation could be made responsible for any hypothetical dissipation. The overall conclusion in the simplest case was that electrons are emitted from the nucleus (in beta disintegration of a single species) with energies having all values from zero up to a characteristic maximum for the species. This was in strongest contrast with the situation in alpha disintegration. At that time it was believed that alpha particles for a given species are emitted with precisely the same energy from all disintegrating nuclei. In terms of experimental evidence the principle of energy conservation seemed in doubt for beta disintegration.

During the period 1927–31 data were accumulating on the rotational attributes of nuclei. Concepts of intrinsic nuclear angular momentum and magnetic moment had been validated in terms of the detailed optical features of atomic and molecular spectra (see NUCLEAR MOMENTS). The generalization emerged that the quantum number specifying the resultant angular momentum of a nucleus is integral or half-integral as the mass number of the nucleus is even or odd. The spin quantum number of the electron had already been accepted as $\frac{1}{2}$, supported by Dirac's theory of 1928. Angular momentum (as well as energy) empirically appeared not to be conserved in beta disintegration; nuclear mass number does not change in this process, so the change in angular momentum quantum number must be integral—but for the emitted electron the angular momentum quantum number is half-integral.

Pauli's neutrino hypothesis was an attempt to salvage the challenged conservation laws. He suggested (1931) that beta disintegration involved the simultaneous emission of an electron and an uncharged particle of small mass (possibly zero) and half-integral spin. In the simplest case (e.g., Bi^{210}), a perfectly definite amount of energy would be shared by these two particles. The name neutrino was introduced by Fermi when he began to incorporate Pauli's idea into a thoroughgoing theory of the process.

Fermi's theory (1934) stems from the assumption that negative beta disintegration consists in the transformation of a neutron into a proton within a nucleus. A negative electron and a neutrino are created in this elementary process "much as a quantum of light is created at the moment of emission from an excited atom." (The simile had been used before the neutrino hypothesis by V.

Ambarzumian and D. Iwanenko, 1930.) Fermi showed how to calculate the relative probabilities of the sharing of a constant amount of energy between the two disintegration particles (giving effectively the form of the continuous energy spectrum of the disintegration electrons), and how to relate the absolute probability of disintegration per unit time (the disintegration constant) to the total disintegration energy and other parameters. Predictions from the theory conformed with experiment; in particular, the many-valued relation between disintegration constant and available energy (many-valued, depending on the change of nuclear angular momentum involved) accorded well with the empirical generalization of B. W. Sargent (1933) relating these quantities for natural beta emitters.

Discovery of positron emission and orbital-electron capture added support for the general validity of Fermi's theory. It was possible to describe both processes, and to evaluate their relative probabilities when they were in competition, by regarding each as involving the transformation of a nuclear proton into a neutron; the former by capture of a negative electron from a state of negative energy and emission of a neutrino, and the latter by capture of an electron from an extranuclear bound state with neutrino emission.

For twenty years after publication of Fermi's theory the free neutrino remained undetected. In 1935 the experiments of M. E. Nahmias suggested that the range of a 1-Mev neutrino in lead is greater than 10^6 km. if energy loss is by ionization only. From 1942 on, experiments reviewed by O. Kofoed-Hansen (1955) showed that linear momentum is not conserved in electron-involved nuclear processes unless neutrino emission be postulated. These results merely brought to focus the apparent nonconservation that led to Pauli's hypothesis; they were hardly convincing empirical evidence of the neutrino. Experimentalists were thrown back on the early suggestion that a neutrino might interact only with an atomic nucleus in the direct reverse of beta disintegration. Such reverse beta disintegration is highly improbable since it requires simultaneous nuclear capture of an electron and a neutrino. Also, conditions under which it might occur depend on whether the particle-antiparticle distinction applies to the neutrino (see ANTIMATTER). If the distinction is relevant, then the neutrino from negative beta disintegration will be captured only along with a negative electron (or only when a positron is emitted); the neutrino emitted in positron disintegration (or in electron capture) will be captured only when a negative electron is simultaneously emitted.

Development of nuclear reactors promised intense sources of (hypothetical) neutrinos from negative beta disintegration, opening the possibility of investigating nuclear capture of free neutrinos. A reactor at a steady power of 1 megawatt yields about 2×10^{17} negative beta disintegrations per second; F. Reines and C. L. Cowan used such a source finally to demonstrate neutrino capture in hydrogen (1954). They recognized this process by recording (in correct time sequence) the annihilation quanta resulting from final disappearance of the positron, and the quanta resulting from ultimate capture of the neutron, produced in the process. About a ton of water provided the hydrogen target for neutrino radiation, and a cadmium salt dissolved in the water served for neutron capture. These investigators failed earlier to find evidence of production of Ar^{37} from Cl^{37} under pile-neutrino irradiation. For this to have occurred a neutrino from negative beta disintegration would have had to condition the emission of a negative electron in the act of capture by a chlorine nucleus. This earlier negative result coupled with the later positive evidence of neutrino capture strongly supported the idea of a significant distinction between neutrino and antineutrino.

As soon as it was established (Chadwick and Goldhaber, 1935) that the neutron mass is greater than that of the neutral hydrogen atom, it was a corollary that the neutron itself is beta active. Not until intense sources (nuclear reactors) became available, however, was direct evidence possible; even then, experimental difficulties were considerable.

J. M. Robson (1951, 1958) detected protons recoiling from beta disintegrations taking place in a beam of thermal neutrons

traversing an observation chamber; in terms of the flux of neutrons, their known velocity distribution, and length of path under observation, he determined the half-life as 12.8 ± 2.5 min. He determined the energy spectrum of observed beta particles coincident in time with the recoiling protons, showing that it was continuous, of normal type, and of maximum energy 782 ± 13 kev (thousand electron volts). Robson later investigated the angular correlation between the directions of electron and proton emission. Beta disintegration of the neutron being the prototype of all such disintegrations, the first test of relevant theory is that it should describe the process in full detail; but even the results of 1958 were neither sufficient nor precise enough to remove all ambiguities in the basic theory.

Hitherto, beta disintegration has been discussed only in the simplest case in which no gamma radiation is emitted; however, beta-active species devoid of gamma radiation are only a small fraction of known beta emitters. When gamma radiation is emitted the electron spectrum of the beta-active source in general contains groups of lines indicating electrons of well-defined energies. Rutherford, Robinson, and Rawlinson (1914) already had made it appear very likely that these electrons originated in the absorption (within the atom of origin) of the energy of gamma-ray quanta. When, as was generally more probable, the quanta escaped from the disintegrating atom, they gave rise (by absorption in surrounding atoms) to photoelectrons with a very similar spectrum of isolated lines. Thus the line spectrum was interpreted as indicating internal photoelectric absorption of the gamma radiation in the radioactive atom.

These interpretations were confirmed. In a many-lined spectrum such as that from radium active deposit, Ellis (1921) detected a repeating pattern with constant energy difference between pairs of lines, the intensities of which showed an apparently constant ratio. He identified this difference as characterizing the ionization energies of the electrons of the K and L shells of the emitting atom, concluding that these line pairs represented photoelectrons ejected by monochromatic gamma rays from the two most tightly bound atomic shells. Consistent with this, he identified the lines corresponding to internal absorption in the less tightly bound M, N, . . . shells in certain cases.

Ellis and Wooster (1925) verified this interpretation by showing that the values of characteristic ionization energies (W_K , W_L , . . .) were those appropriate to the daughter, rather than the parent atom, for the beta disintegration concerned. In this way it was concluded that the emission-and-internal-absorption of the gamma-ray quantum occurs after the disintegration electron has left the nucleus.

Although the basically valid notion of internal photoelectric absorption of gamma radiation had been widely accepted in 1920, there was less unanimity regarding where the gamma rays originate within the atom. Ellis (1922), and later he and H. W. B. Skinner (1924), provided the first circumstantial evidence. Calculating the quantum energies E_γ of the gamma rays, from the electron energies E_e , using the general expression

$$E_\gamma = E_e + W_{K,L} \dots$$

Ellis and Skinner showed that the gamma-ray energies themselves provided several examples of the simple Ritz combination rule: $E_{\gamma 1} = E_{\gamma 2} + E_{\gamma 3}$. From this they concluded that the emitting system must be characterized by well-defined energy states; and, since the excitation energies of states so revealed were entirely different from those known for extranuclear states of the atom, they were interpreted as quantum states of the nucleus. The view was never seriously contested; in the 1960s the view was that whenever beta and gamma radiation originate in the same pure source, then the daughter nuclei from primary disintegration are left in one or more states of excitation (possibly in the ground state also) from which they eventually revert to ground state by emitting gamma-ray quanta (or by transferring the energy to internal-conversion electrons). When gamma rays are emitted by positron-active or by capture-active species, similar statements are appropriate.

The primary process in the general case of beta disintegration

is now seen to be of some complexity. The initial nuclei are all in the same energy state, but many energy states of the final nucleus have to be considered. The partial processes by which particular final states are produced are mutually exclusive competing modes of disintegration of the parent species. The available energies Q_0 , Q_1 , Q_2 , . . . are different, and each mode is independently characterized by a partial disintegration constant λ_0 , λ_1 , λ_2 , The empirical (total) disintegration constant for the species is given by the sum of these partial disintegration constants (compare equation [2]), and the overall energy spectrum of the disintegration electrons is compounded of the partial continuous spectra appropriate to the individual modes. This view was first explicitly given by Ellis and N. F. Mott in 1933; in such a case Fermi's theory is concerned with the values of λ_τ and Q_τ (and other parameters specifying the transition) when each mode is considered independently.

Unraveling the complex continuous spectrum in the general case may call for quite sophisticated methods of experimentation. Gamma-ray processes for partial disintegration modes that populate all final states except the ground state are generally rapid in relation to the resolving times of particle-detector electrical circuits. Genuine prompt coincidences are to be expected between pulses in one detector that records gamma-ray quanta of given energy (or the corresponding internal conversion electrons), and another that detects disintegration electrons, only when the latter electrons belong to the partial spectrum or spectra associated with the gamma rays under observation. Developments of older coincidence methods on this basis (Bothe and others, 1935, 1937; Feather, 1940) have greatly increased the possible range of experiment. More recent improvements in electronic techniques permit direct determination of gamma-ray lifetimes (of the order of 10^{-10} sec.) by the method of delayed coincidences, in suitable cases.

Experimentally (though not theoretically) orbital-electron capture poses problems very different from those of beta disintegration. In the general case the most easily observed emissions from a capture-active body are likely to be gamma radiations corresponding to partial modes in which the daughter nucleus is left with energy of excitation. In the simplest case, when there is no gamma radiation, there are only fluorescent X rays, Auger electrons (alternatively emitted through partial internal conversion of the energy of inner-shell excitation into electron energy; see PHOTOELECTRICITY), inner bremsstrahlung (see below), the recoiling atom of the daughter product, and the neutrino (emission of which is mainly responsible for that recoil). None of these emissions is easy to detect with species of small Z ; they have been mentioned here in approximate order of increasing difficulty of detection, whatever the value of Z .

Experimental observations establishing occurrence of capture should be distinguished from observations through which values of disintegration energy may be deduced. Detection of fluorescent X rays or Auger electrons provides no information about disintegration energies; to that extent the less difficult observations are also the less informative.

A brief history of improvements in fluorescent X-ray detection (and energy measurement) can be given in a few examples. In 1939 H. Walke, E. J. Williams, and G. R. Evans detected K-shell X rays resulting from electron capture in V^{49} ($T = 330$ days) in a Wilson cloud chamber and showed that the rapid absorption of this radiation in the chamber gas was consistent with its assumed quantum energy (4.5 kev). In 1949 B. Pontecorvo, D. H. W. Kirkwood, and G. C. Hanna detected and identified in terms of their energy (250 ev) the L-shell X rays resulting from electron capture in Ar^{37} ($T = 34$ days) in a proportional counter. They established (by comparative experiments using counters containing argon and xenon, respectively) that this L radiation is both primary and secondary in origin. The secondary component is the result of atomic rearrangement that takes place after K radiation has been emitted; they saw the primary component as resulting from L-electron capture operating as an independent nuclear process competing with the (more probable) capture of an electron from the K shell. In 1957 J. Scobie and G. M. Lewis

pushed the limit toward lower energies, detecting the K radiation of boron emitted as a result of electron capture in C^{11} ($T = 20.4$ min.). They were able to introduce the radioactive material into their proportional counter as a gas, as in the other case cited, but their detection problem was more difficult because 99.8% of disintegrations of C^{11} proceed by positron emission. An anticoincidence arrangement, discriminating against the much more numerous positrons, had to be used.

In respect of the inner bremsstrahlung, P. Morrison and L. Schiff (1940) noted that the sudden redistribution of electric charge in an atom in which electron capture occurs should lead (with small probability) to emission of a quantum of radiation, the energy of which is thus not available to the emitted neutrino. The corresponding effect in beta disintegration had been discussed theoretically by J. K. Knipp and G. E. Uhlenbeck (1936). Inner bremsstrahlung associated with electron capture (in Fe^{55}) was first observed by H. Bradt and collaborators in 1946. Its intensity was estimated as about 3×10^{-5} quantum of 70 kev average energy per disintegration. The first rough spectral analysis of the Fe^{55} radiation was made by scintillation spectrometer (D. Maeder and P. Preiswerk, 1951); the observed spectrum was continuous, as predicted. Quantum intensity per unit energy interval theoretically should increase in a roughly parabolic way as the energy falls below a limiting value equal to total disintegration energy. Thus disintegration energy should be derivable by a linear plot of the high-energy end of the bremsstrahlung spectrum. Maeder and Preiswerk deduced a value of 206 ± 20 kev for the capture disintegration energy of Fe^{55} in this way; a more precise value (217 ± 10 kev) was obtained by P. R. Bell, J. Jauch, and J. M. Cassidy (1952) by the same method. Scintillation spectrometers have since been applied to the spectral analysis of inner bremsstrahlung from many other capture-active bodies. This method (difficult in that intensity of effect is so low) becomes more difficult when capture transformation also involves emission of nuclear gamma rays; in certain cases even this has been overcome (e.g., R. G. Jung and Pool, 1956).

Most of the disintegration energy released in electron capture is carried away by the emitted neutrino. If transformation occurs between well-defined nuclear states, the kinetic energy of the neutrino should be single valued for any particular mode, apart from such trivial secondary effects as inner bremsstrahlung. Correspondingly, when the final nucleus is left in the ground state the recoil energy of the daughter atom should also be single valued. (When the final nucleus is left in an excited state it suffers successive recoil from neutrino and gamma-ray emission.) The earliest investigations of recoil (J. S. Allen, 1942) were primarily to study the overall balance of linear momentum; with the neutrino no longer hypothetical, more precise determination of recoil energy can be taken as determining the neutrino energy (or the disintegration energy) in suitable cases. Assuming the rest mass of the neutrino is zero, a nucleus of mass number A emitting a neutrino of kinetic energy T (Mev) must recoil with energy $540 T^2/A$ (ev). In 1952 G. W. Rodeback and Allen used a time-of-flight method to determine the velocity of recoil of Cl^{37} produced in the capture disintegration of Ar^{37} in a gaseous source. On the above assumption they obtained $T = 0.8 \pm 0.1$ Mev in this case. Two years later accuracy was increased by more than an order of magnitude; Kofoed-Hansen ingeniously crossed electric and magnetic fields in a double guard-ring condenser to obtain $T = 806 \pm 8$ kev for the same disintegration. This value shows excellent agreement with that calculated (816 ± 4 kev) from the energy balance of the production reaction $Cl^{37}(p,n)Ar^{37}$.

As has been implied, the overall probability of capture disintegration involves contributions corresponding to capture of electrons from the K, L, M, . . . shells. If any of these electrons suffers rearrangement (as in chemical combination) its contribution to the overall probability of capture must change. The effect must be small even when atomic number is small, but it has been experimentally detected for Be^7 . Showing results of earlier investigators to have been inconclusive, J. J. Kraushaar, E. D. Wilson, and K. T. Bainbridge (1953) carefully compared the decay

of Be^7 sources in the form of metal, oxide, and fluoride, combining these in their three possible pairs. Taking the disintegration constant determined for the metallic sample as standard, they found that of the beryllium fluoride sample to be less by 7.4 ± 0.5 parts in 10^4 , and that of the beryllium oxide sample to be less by 1.3 ± 0.5 parts in 10^4 . In agreement with these results the directly determined disintegration constant of the oxide was 6.1 ± 0.6 parts in 10^4 greater than that of the fluoride. The effect is in the direction anticipated from considerations of molecular structure; the more completely the two valence (*q.v.*) electrons are removed from the beryllium atom the smaller the overall probability of electron capture by the nucleus. These experiments were the first to exhibit limitations of the classical dictum that radioactivity is entirely uninfluenced by chemical combination; on the other hand they demonstrate how nearly accurate this categorical statement is, even in the most extreme situations encountered in the laboratory. Quite another order of disturbance of "normal" conditions has to be envisaged for the interiors of stars; in such circumstances (chemical combination being now irrelevant) an altogether greater effect is to be anticipated.

To consider the origin of this effect in quantitative terms, suppose that a nucleus of charge number Z is transformed by an electron-involved process into a nucleus of charge number $Z + 1$, or $Z - 1$. In either case the strength of binding of the extranuclear electrons changes (the original system being assumed to be a neutral atom with its full complement of electrons). In the $Z + 1$ case the energy of binding increases, in the $Z - 1$ case it decreases. Thus, in the former case energy must be liberated, in the latter energy must be absorbed by the extranuclear electron system. The amount of this energy is approximately $150 Z$ (ev) (G. Allard, 1948; L. L. Foldy, 1951)—more than 12 kev when $Z > 80$. When energy must be absorbed by the extranuclear system (the case in positron emission and electron capture), that the process takes place spontaneously at all indicates that energy is supplied at the expense of the products of disintegration (essentially, at the expense of the kinetic energy of the neutrino).

Conversely, energy liberated by the change in binding (as it must be in negative beta disintegration) should become available for the nuclear process. There are at least two beta-active species (Pb^{210} and Ra^{228}) among the natural radioelements for which the energy of negative beta disintegration in the most probable mode (under laboratory conditions) is of the same order as $150 Z$ (ev). If atoms of these species existed in the body of a bright star, they would be almost completely ionized. The half-life for beta disintegration of the bare nucleus then would be many orders of magnitude greater than that of the neutral atom; indeed, the bare nucleus might be beta stable (knowledge of the energies involved was not sufficient to state this with certainty in 1965). That would be an extreme consequence of an absolute kind.

XI. ALPHA DISINTEGRATION

Compared with beta disintegration, alpha disintegration is relatively simple. For more than 25 years after the first magnetic and electric deflections were made of alpha particles, no observations contradicted the conviction that alpha particles from disintegration of a pure species are all emitted with the same velocity. Admittedly, velocity often had to be estimated from the measured range of the particles in air under standard conditions, but when more powerful methods could be used the generalization still seemed to hold. On this view, the only measurable quantities for any alpha emitter were the range of the particles (or velocity, or disintegration energy) and the disintegration constant (or half-life). Having considerably improved the measurement of range, in 1911 Geiger and J. M. Nuttall produced convincing evidence that these two quantities are significantly related. In terms of disintegration energy Q_α , the relation stated by Geiger and Nuttall can be written

$$\log \lambda = A + B \log Q_\alpha \quad (10)$$

where the empirical value of B is about 80.

At face value, equation (10) suggests a power-law dependence of λ on Q_α , with an exponent of about 80. The Sargent relation that connects observed values of λ and Q_β , when expressed in the same form, suggests a power-law dependence with exponent of roughly 5 or 7, according to type of beta disintegration. The contrast is striking in practice or theory. In the latter connection the significant power laws in physics (1960s) almost universally involve rational powers of the independent variable not many times greater than one: a 5th-power law is a rarity, an 80th-power law almost absurd. But these considerations did not figure conspicuously in the 1920s. With no satisfactory theory of alpha disintegration the original form of the empirical regularity commonly was accepted without question. R. Swinne (1912, 1913) suggested the fundamentally less objectionable form

$$\log \lambda = C + DQ_\alpha^{\frac{1}{2}} \quad (11)$$

but without theoretical justification.

By 1930 theoretical and experimental aspects of alpha disintegration had been revolutionized. In 1928 Gamow and, independently, R. W. Gurney and E. U. Condon provided the basis of an acceptable theory; in 1929 S. Rosenblum obtained the first evidence contradicting the over-simple experimental picture.

The difficulty besetting any theory of alpha disintegration in terms of classical mechanics (*q.v.*) is illustrated in experiments on scattering and disintegration involving uranium and plutonium. Pu^{239} emits alpha particles of 5.15 Mev maximum energy, the daughter being U^{235} . At the instant it is just breaking from the nucleus the alpha particle (in classical mechanics) cannot have kinetic energy less than zero. As the alpha particle recedes, its kinetic energy should increase under repulsion between its own positive charge and the charge on the residual nucleus U^{235} . The experimental result implies, however, that the increment in energy derived in this way cannot be greater than 5.15 Mev, and, if the field is a coulomb force (see *ELECTRICITY: Coulomb's Law*) over the whole range involved, that the separation of the centres of alpha particle and residual nucleus at the instant of release cannot be less than 5.14×10^{-12} cm. Experiments on the scattering of alpha particles by uranium were carried out by Rutherford and Chadwick in 1925. If these can be regarded as referring to U^{235} , as is certainly the case, they show that the repulsive field is indeed coulombian, but from 3.02×10^{-12} cm. outward (alpha particles of Po^{212} of 8.78 Mev energy were employed). The scattering experiments show all of the region beyond 3×10^{-12} cm. from the centre of the U^{235} nucleus is devoid of nuclear matter; in escaping from the Pu^{239} nucleus the alpha particle must pass through this region, yet on emerging it is found paradoxically to have much less energy than expected. The paradox may be posed as a question: if an alpha particle with nearly 9 Mev of kinetic energy is turned back in the repulsive field so that it is unable to enter a U^{235} nucleus at which it is directly fired, how can an alpha particle ever escape that nucleus when little more than 5 Mev of energy is available for disintegration? Within the original nucleus it must be held in an essentially attractive field; more than the total available energy must be required to overcome that attraction before the alpha particle reaches the region of repulsive field through which it can escape.

This paradox was seen by Gamow, Gurney, and Condon to characterize a general situation for which wave mechanics gave formal results that differed fundamentally from those according to classical mechanics (see *QUANTUM MECHANICS*). Classically, a region in which the total energy of a particle is less than its potential energy in the field is forbidden; according to wave mechanics this prohibition is never absolute. If the classically forbidden region is not too large in extent, and if the energy deficit is not too great within the region, the particle wave will leak through. This idea had already been applied earlier in 1928 to the problem of the field emission of electrons from metals by L. Nordheim and J. R. Oppenheimer; the problem in relation to alpha disintegration was seen to be essentially similar. Alpha disintegration, then, is basically a nonclassical process; calculation of the disintegration constant in any case is primarily a matter of de-

termining the penetrability of the potential barrier that by classical mechanics should confine the alpha particle within the nuclear system indefinitely. In its simplest form the result of these calculations was not unlike equation (11) with the important conclusion that the parameter D in that equation is proportional to the charge number of the residual nucleus.

Rosenblum (1929) was first to apply magnetic focusing to the examination of alpha-particle spectra. For lack of sufficiently intense magnetic fields of large enough spatial extent, earlier investigators had been restricted to the much less powerful direct deviation method. Having an opportunity to work with a large general-purpose electromagnet at Bellevue (Paris), Rosenblum quickly discovered a previously unsuspected fine structure in the alpha-particle spectrum of Bi^{212} (ThC). Instead of a single sharp line, there appeared to be at least four lines attributable to this species. This precipitated attacks on the problem elsewhere, particularly in Cambridge, Eng., where equipment was developed specifically for this purpose. The differential ionization chamber (Rutherford, F. A. B. Ward, and W. B. Lewis, 1931) provided a high-resolution device for the measurement of particle ranges, and a specially designed semicircular focusing magnet (Rutherford, C. E. Wynn-Williams, Lewis, and B. V. Bowden, 1933) more than matched in performance the much larger instrument in Bellevue. Very soon it was established that the alpha disintegration of many of the naturally radioactive species is complex. By the 1960s the gridded pulse ionization chamber and the semiconductor total ionization counter had largely superseded earlier energy spectrometers for man-made species of large Z ; their use merely reinforced the conclusion (already forming in 1940) that it is the exception rather than the rule for the radiation from a pure alpha-active species to consist of particles of single energy only.

Explanation of complex alpha disintegration was first given by Gamow in 1930; previously, not much attention had been paid to the generally feeble gamma radiation observed with some alpha emitters. Compared with that associated with beta disintegration, this gamma radiation was not only of low intensity in most cases but it was also of low quantum energy. Only Meitner and her collaborators (1924–28) had investigated this field systematically. Gamow offered the view that gamma rays should be associated with all alpha disintegrations for which the energy spectrum is complex. He ascribed the line of maximum energy in any complex spectrum to the alpha particles of the partial disintegration mode in which the daughter nucleus is produced in the ground state; the other lines he regarded as evidence for partial modes giving rise to excited states of the product—and so to gamma rays. (This was the forerunner of a similar suggestion Ellis and Mott made three years later in relation to complex beta disintegration.)

Gamow supported his suggestion by examples of numerical agreement between observed values of gamma-ray quantum energies and differences in observed particle-disintegration energies; more substantial support came from experiments by Ellis (1932) with Bi^{212} . Thereafter, the basic notion of competing partial modes of disintegration was accepted. To interpret the many complex alpha disintegrations that have since been found, Gamow's original description had to be generalized only in one respect. In a small minority of cases it appears that the ground state of the daughter nucleus is not significantly populated by any one of the primary modes of particle disintegration that occurs. In such cases the emission of a gamma-ray quantum (or a corresponding internal conversion electron) follows emission of the alpha particle in every instance.

The fact that complex alpha-particle spectra show fine structure (*i.e.*, particle-disintegration energies for the partial modes of a given species are not very different—perhaps varying within a 10% range) is a consequence of the rapid variation of disintegration probability with energy to which equation (10) first drew attention. But it is also a fact that in any one fine-structure spectrum the intensities of the lines and their energies may exhibit no obvious correlation; thus, as Gamow pointed out, some parameter besides the energy must determine disintegration probability.

That the change in angular momentum between initial and final nuclear states should be one such parameter was at once accepted (the disintegration probability being less, the more angular momentum the alpha particle has to carry away). However, this does not seem to be the only additional parameter. Reference has been made to the almost complete suppression of the energetically most favoured modes in certain cases; such an extreme effect could not result from unfavourable spin change alone. Alpha disintegration is empirically simpler than beta disintegration, in that discrete energies are observed; it is theoretically simpler in that only heavy particles are involved; but, it is far from simple in detail. A heavy nucleus is a complex system of many particles, and it is unrealistic to suppose that its behaviour can be fully described in simple terms.

The statement that all species with $Z > 83$ are intrinsically alpha unstable refers to nuclei in the ground state. Energy available for alpha emission from an excited state of a heavy nucleus is necessarily greater than from ground state, perhaps enough for alpha emission to compete significantly with normal deexcitation (gamma-ray quantum emission). These considerations underlie the interpretation (Feather, 1929) of long-range alpha particles, a rare disintegration effect first reported with thorium active deposit by Rutherford and A. B. Wood in 1916. A similar effect was found with the active deposit of radium a few years later; in 1965 these remained the only well-attested examples. The nuclei Po^{212} (ThC') and Po^{214} (RaC') in ground state have more energy available for alpha disintegration than any other naturally radioactive nuclei; as a result of the preceding (beta) disintegrations, they are sometimes left in states of considerable excitation (particularly RaC'). Competition between alpha and gamma emission from these states is such that about 220 long-range alpha particles are observed overall per million normal (ground-state) alpha particles from ThC' , and about 30 long-range per million normal from RaC' . Three separate groups of particles were found with ThC' , and 12 with RaC' (Rutherford, Lewis, and Bowden, 1933); critical examination of relevant gamma-ray spectra (Ellis, 1934) verified the interpretation given.

XII. SPONTANEOUS FISSION

The distinction between absolute and empirical stability limits has been stressed for alpha disintegration. An obvious limit occurs between $Z = 82$ and $Z = 83$: with very few exceptions, naturally occurring nuclei with $Z < 83$ are alpha stable; in an absolute sense, however, very many with Z from 60 to 82 are alpha unstable.

All heavy nuclei are unstable in an absolute sense for other processes that are not observed. For example, U^{234} emits five alpha particles in succession in producing Pb^{214} ; 26.2 Mev of energy are set free in these disintegrations. Five alpha particles go to make up the nucleus Ne^{20} which, if formed by such alpha-particle aggregation, would liberate an additional 19.3 Mev. Altogether then, 45.5 Mev are available for $\text{U}^{234} \rightarrow \text{Pb}^{214} + \text{Ne}^{20}$, yet this process is not observed.

There is nothing fundamentally mysterious about this result: calculation of potential-barrier penetration probabilities on the basis of any reasonable assumption shows the improbability, to the point of inconsequence, even of $\text{U}^{234} \rightarrow \text{Ra}^{226} + \text{He}^4$ (for which 9.5 Mev of energy are available) compared with normal alpha disintegration of U^{234} (for which only 4.86 Mev are available).

It is unlikely that such considerations were seriously entertained before 1940, although all the needed numerical evidence (alpha-particle energies and nuclear masses) had been accumulated with enough accuracy for predictions to be made. When neutron-induced fission was discovered in 1939, it came as something of a shock to most physicists to recollect that the heaviest nuclei are absolutely unstable (to the extent of nearly 200 Mev) in respect of division into two roughly equal fragments. The newly discovered fact was that this process of division becomes "instantaneous" (with the compound nucleus U^{236}) when no more than about 6.4 Mev (the energy of binding of the last-added neutron) is given to the system. This, indeed, was the important result.

Perhaps physicists were not so entirely forgetful of the extent of the absolute instability of the heaviest nuclei in respect of this hypothetical process; what they had no means of knowing was that the height of the potential-energy barrier opposing the process was so little greater than the available energy. As soon as this fact was given by experiment Bohr and J. A. Wheeler (1939) pointed out that spontaneous fission was to be reckoned with experimentally. It was first detected in natural uranium by Petrzhak and G. N. Flerov in the following year.

In 1965 spontaneous fission had been established as a partial disintegration mode for about 35 species with $Z > 90$. For a few species it appears to be the predominant mode. Spontaneous fission generally is more probable by a factor of about 10^4 for species of even A and even Z than for neighbouring species of odd A , or even A and odd Z . According to the simplest theoretical model of the process the probability should depend on the value of the fissionability parameter Z^2/A ; however, for even A and constant (even) Z , the facts do not bear out this prediction. For each such value of Z the partial disintegration constant for spontaneous fission shows roughly parabolic variation with A , passing through a minimum when the number of excess neutrons ($A - 2Z$) is 52. On the other hand, if attention is concentrated on the behaviour of the species of maximum beta stability, for each value of Z , a monotonic variation of partial disintegration constant with Z^2/A is obtained (Feather, 1964). Empirically for such species

$$\log \lambda = E + FZ^2/A \quad (12)$$

These results can be extrapolated only tentatively beyond the observational range from which they were drawn. On the basis of equation (12), with constants E and F taken from experiment, $Z^2/A = 41.65$ when $\lambda = 10^0/\text{sec.}$; $Z^2/A = 43.5$ when $\lambda = 10^{20}/\text{sec.}$ These values of λ correspond approximately to the limits of possible experimental detection and absolute instability, respectively. With $A = 3Z - 48$ (roughly appropriate for species of maximum beta stability in this range of Z) the limiting values of Z become 106 and 112. On this basis, if the extrapolation were accepted, it would be concluded that even-even species of maximum beta stability would be too short-lived in respect of spontaneous fission to be identifiable experimentally when $Z > 106$, or to be considered capable of independent existence at all when $Z > 112$. It should be repeated that neighbouring species of odd A would tend to be significantly more stable—and that for a given (even) Z there would also tend to be other species of even (and smaller) A somewhat more stable in respect of spontaneous fission—than the representative species of maximum beta-stability to which the empirical equation (12) has been assumed to apply. Such considerations represent the most that could be said in the 1960s regarding the problem of the natural number of the elements that was first posed by Turner in 1940.

Spontaneous fission has been most widely studied with Cf^{252} ; this beta-stable body of half-life 2.2 yr. exhibits a 3% spontaneous fission mode in competition with alpha disintegration. Details of the process are very similar to those of thermal-neutron-induced fission of U^{235} and Pu^{239} . The mass-yield curve for the fission fragments shows the same double-peaked structure as in the more familiar case (with the valley between the peaks somewhat more pronounced); there are secondary neutrons and long-range alpha particles characterized by energy spectra almost indistinguishable from those applicable in low-energy induced fission (though with absolute intensities somewhat greater for $Z = 98$, than for $Z = 92$ or 94). Studies with other species emphasize this similarity.

Spontaneous fission is theoretically a barrier-penetration process, but the significant details of the barrier are not so easily specified as in alpha disintegration. Nor is the broadly satisfactory approximation for alpha decay, that the structure of the residual nucleus is unimportant, permissible in fission where disintegration particle and residual nucleus cannot be sharply distinguished. In fission, too, the saddle-point configuration (that of maximum potential energy) is definitely one of less than final

distortion; actual scission occurs later in the process. This last makes it possible to imagine the distribution of mass and charge between the fragments as being determined (statistically) after fission has become "inevitable" for any particular nucleus. Thus the disintegration constant for spontaneous fission is not expressed as the sum of many terms (representing partial mass-modes), but as the sum of very few terms that correspond to possible fission channels effective through the saddle point. What happens once the saddle point is passed (e.g., what fragments are formed, their energy of excitation, number of neutrons emitted from each, what gamma rays) is a matter for description in other terms.

Two species for which spontaneous fission is the only observed disintegration mode are Cf^{254} ($T = 61$ days) and Fm^{260} ($T = 2.7$ hr.). Spontaneous liberation of energy by the latter amounts to about 5 megawatts per gram of the pure species; at 1.5×10^{-7} molar concentration (aqueous) its energy of decay would evaporate the solution to dryness. These figures indicate the great difficulties involved in collecting such species in weighable or visible amount.

In the stars the situation is different; L. B. Borst suggested (1950) that a peculiar feature of the light curve of type I supernovas (see NOVA AND SUPERNOVA) required identification of a radioactive decay with half-life about 55 days that might be effective on a large scale in the exploding star. The peculiar feature is that, from about 100 days after the initial outburst, light emission from these stars falls off exponentially with about that period (W. Baade, 1945, 1956). In 1956 G. R. Burbidge, E. M. Burbidge, *et al.*, offered spontaneous fission of Cf^{254} as a plausible explanation. They conjectured that the supernova was a relatively cold star that had collapsed, transforming gravitational into thermal energy; that multiple neutron capture had then produced a sudden buildup of heavy elements; and after a time the dominant (temporary) source of energy was the Cf^{254} that remained. This is an attractive suggestion, even though it requires the production of about 10^{29} grams of Cf^{254} in each stellar outburst (E. Anders, 1959; P. Fong, 1960).

XIII. DECAY OF LONG-LIVED EXCITED STATES OF NUCLEI

Species distinct in radioactive properties but with the same mass and charge numbers are called nuclear isomers. The phenomenon was envisaged as a possibility by Soddy in 1917, and first observed by Hahn in 1921. Elucidation of the main disintegration sequence

by Fajans (1913) has been described earlier. In 1921 Hahn found a second beta-active daughter of UX_1 , considerably longer-lived ($T = 6.7$ hr.) than UX_2 , and of much lower activity when in equilibrium with its parent. This product (which he named uranium Z) was chemically inseparable from UX_2 , and Hahn concluded that both were the same protactinium isotope Pa^{234} —only that the same constituent particles of each nucleus were differently organized. Although Hahn's observation was of a previously unrecognized phenomenon, it aroused little interest until many more examples of isomeric pairs were found among the products of man-contrived transmutation.

The first case of man-made nuclear isomerism identified was with an isotope of bromine. Common bromine has two stable isotopes of mass numbers 79 and 81. Slow-neutron bombardment produced three activities of half-lives 18 min., 4.4 hr., and 36 hr. (Fermi and B. Kurtchatov, and their respective collaborators, 1935); gamma irradiation also yielded three activities of half-lives 6.4 min., 18 min., and 4.4 hr. (Bothe and Gentner, 1937). Slow-neutron bombardment of medium- Z elements normally results exclusively in (n, γ) processes, low-energy gamma irradiation giving (γ, n) transformations. Therefore the activities of half-lives 18 min. and 4.4 hr. were both ascribed to Br^{80} ; subsequent investigation substantiated this conclusion. In 1965 about 200 isomeric pairs were known—though the precise total turns on a convention of definition (see below).

Nuclear isomers justify their name in that the same numbers of neutrons and protons are held to be differently arranged in two nuclei that are isomeric. The two configurations can be regarded as two energy states of the nuclear system; one is usually the ground state. The other configuration differs only in lifetime (longer than normal) from any other excited state of the given nucleons. Experiment has thoroughly vindicated C. F. von Weizsäcker's suggestion (1936) that the long lifetime results because the ground state and its isomeric state differ in angular momentum by more than two quantum units. Then, if there is no state of intermediate energy through which more rapid cascade deexcitation is possible, and particularly if the excitation energy of the upper isomeric state is small, that state will be metastable in relation to gamma-ray emission.

Empirically, isomeric pairs may be classified according to whether the ground-state isomer is stable or unstable; and according to whether the upper-state isomer transforms predominantly by particle emission, or reverts to a lower state by isomeric transition. Since isomeric-state excitation energies generally are small when the ground-state isomer is stable, isomeric transition is usually the only possible transformation mode for the upper state of the pair. (Exceptionally, the isomer of naturally occurring Cd^{113} is beta active; but it is almost certain that empirically stable Cd^{113} is beta unstable in absolute terms.) When the ground-state isomer is unstable, enough energy is available for an upper-state isomer to transform by particle emission also; then, the relative probability of this mode (as against isomeric transition) depends on the details of the situation.

Both members transform predominantly by particle emission in the classical Pa^{234} isomeric pair UX_2 and UZ . Many investigations have been made of these bodies since 1936—without fully resolving all the problems that have arisen! Feather and E. Bretscher (1938) showed that the total disintegration energies are approximately the same, but very differently distributed (hardly any gamma rays from UX_2 ; more than twice as much energy in gamma rays as in beta particles from UZ); that the equilibrium activities are roughly as 99.85% to 0.15%; and that UX_2 is very probably the upper-state isomer. These conclusions later were confirmed and extended. It became clear that the ground-state isomer (UZ) is not formed significantly as a result of the beta disintegration of UX_1 , but that the UX_2 state is produced almost exclusively. This state then suffers branching disintegration, the major mode being the normal beta disintegration (of UX_2), the minor mode (0.18%, according to G. R. Martin and collaborators, 1960) the isomeric transition producing UZ . The energy of the isomeric transition was estimated as about 60 kev (S. Bjornholm and O. B. Nielsen, 1962), and the large change of angular momentum associated with it is seen as responsible for the great difference in beta-disintegration modes of the isomers (for which the various final states of the product nucleus are very differently available because of angular momentum selection rules). The UX_2 beta disintegrations proceed largely to the low-lying states of the product U^{234} , the UZ beta disintegrations to states of high excitation (for which the corresponding spin change is more favourable). From these states of high excitation the gamma rays of UZ are emitted in cascade.

When "isomeric" transition (to a stable or unstable ground state) is predominant, the decision that the case actually qualifies as one of isomerism is a matter of convention. It is a question of the relation between the lifetime of the gamma-ray transition involved and the resolution-in-time of the apparatus employed for its investigation. In the end the decision turns on the investigator's ability to recognize the difference in radioactive properties of the two states concerned. Lifetimes of excited states of nuclei vary from 10^{-12} sec. upwards (some are even shorter), and much can be learned from their measurement throughout the range; but empirically it appears desirable to restrict the term isomeric to transitions with a range of lifetimes much narrower than the measurable. Internal conversion empirically becomes considerably more prominent in relation to gamma-ray emission as the difference in angular momentum between nuclear levels increases. The larger this difference, the more completely does the

radiation emitted in an isomeric transition consist of electrons, and the more comparable the case is with that of a beta emitter, except that the spectrum energy of the electrons is a line spectrum rather than a continuum. In the recognition of distinctive radioactive properties, therefore, it is most realistic to make the comparison between an isomeric transition and a beta disintegration, and to limit the range of the former (as the latter is limited naturally) to processes of lifetime longer than about 0.01 sec. This would automatically rule out a considerable number of the roughly 200 known isomeric pairs.

Nuclear isomerism generally shows more regularity among species of odd A than among those of even A . In the former group, whether the neutron number N or the proton number Z is odd, isomerism seems likely when the odd nucleon number is just less than one of the shell-closure numbers 50, 82, and 126 (if applicable); and much less likely when the odd nucleon number is just greater than one of these numbers (Goldhaber and R. D. Hill, 1952; Goldhaber and A. W. Sunyar, 1955).

XIV. APPLIED RADIOACTIVITY

There is hardly any pure or applied science that has not advanced since 1945 through the use of man-made radioactive bodies; these bodies also find wide application in industry.

Noteworthy application of naturally radioactive bodies is made in therapy, particularly for cancer (*see* CANCER: Treatment). In 1938 all radium used in the hospitals of the world probably was no more than 1,000 curies. By the 1960s there were 160 therapy units, of 1,000 curies of Co^{60} each, in the U.S. alone; units using 10^5 or 10^6 curies each were predicted within a few years. The half-life of Co^{60} is 5.23 yr.; and its gamma-ray spectrum is much simpler than that of radium and its products, consisting of two basic components (1.17 Mev and 1.33 Mev) of about the same intensity. Absence of gamma rays of smaller quantum energy is an advantage for deep therapy. Million-curie single units were also predicted in the 1960s for Cs^{137} . The gamma radiation from this body is effectively monochromatic (0.66 Mev); its half-life is about 27 yr. These high-intensity gamma-ray sources of long lifetime were almost certain to replace X-ray tubes in the near future for many nonmedical applications also. Cautious advances in therapy with shorter-lived radioactive bodies that are taken up preferentially in certain organs (as iodine is concentrated in the thyroid gland) continued to be made (*see* THYROID GLAND, DISEASES OF).

Radioactive isotopes as tracers of the reaction paths of the stable elements to which they belong were exploited with naturally radioactive lead and bismuth in the 1920s. Success of the method depends upon the fact that (until radioactive nuclear change takes place) the chemical behaviour of the radioactive atom is commonly the same as that of a stable atom of the same nuclear charge. The effect of the radioactivity of the unstable isotope is entirely unspecific and negligible in all but extreme situations; a similar effect would be produced if the system were irradiated by an external source of X rays or gamma radiation of appropriate intensity.

In fundamental chemistry the most extensive field of application of radioactive tracers has been in the study of exchange reactions. Such a reaction may occur when two compounds with one component atom in common are in the same aqueous solution. If initially only one of the compounds contains a tracer isotope of the element held in common, then separation of the two compounds from solution will permit determination (in terms of radioactivity associated with each) of the amount of exchange that has taken place. In this way it has been shown that chlorine exchanges between chloride and chlorate ions, lead between lead nitrate and lead chloride, and that free iodine exchanges with iodide ion. On the other hand, phosphorus does not exchange between phosphate and phosphite ions, nor sulfur between sulfate and sulfite, nor free sulfur with carbon disulfide, nor iodine between iodoform and iodide ion. The method has been widely used to provide information almost impossible to obtain by other means.

The impact of radioactivity on chemistry has been spectacular

in relation to the periodic table, as in the production of trans-uranium elements. In 1934 atomic numbers 43, 61, 85, and 87 were conspicuous gaps in the list of known species. For element 43, the most likely mass numbers of stable isotopes were 97 and 99, but the occurrence of $^{92}\text{Mo}^{97}$ and $^{94}\text{Ru}^{99}$ in nature made it unlikely that either of the former species would in fact be stable. For element 61, mass numbers 147 and 149 (or 145) might conceivably have belonged to stable species, but for the existence of the beta-stable isobars $^{147}\text{Sm}^{147}$ and $^{149}\text{Sm}^{149}$ (or, alternatively, $^{145}\text{Nd}^{145}$). In 1937 C. Perrier and Segrè first produced radioactive isotopes of element 43 by deuteron bombardment of molybdenum. They used this material for tracer study of the chemical properties of the new element, and suggested the name technetium. Technetium is chemically more akin to rhodium than to manganese, its congeners in group VIIa of the periodic table. Three of the isotopes, Tc^{97} , Tc^{98} , and Tc^{99} , are long-lived. Tc^{99} (half-life 2.2×10^5 yr.) is obtained in relatively high yield in uranium fission. In this way it has been prepared chemically pure in gram amounts. Radioactive isotopes of element 61 were first identified by J. A. Marinsky, L. E. Glendenin, and C. D. Coryell in 1947; the element was named promethium on their suggestion. The longest-lived isotope is Pm^{145} ($T = 18$ yr.); the 2.6-yr. beta-active Pm^{147} is separable in weighable amounts by ion exchange from the products of fission. D. R. Corson, K. R. MacKenzie, and Segrè produced the first recognized isotope of element 85 by the bombardment of bismuth with alpha particles in 1940. They suggested the name astatine, and showed that this last member of group VIIb (halogens) exhibits the general behaviour of a metal. The isotope they had produced was At^{211} ; it has a half-life of 7.2 hr., and transforms 41% by alpha emission and 59% by electron capture. The first isotope of element 87 (francium) to be identified was the Fr^{223} Perey recognized in 1939 as a daughter of actinium. Francium behaves as an alkali metal; the perchlorate, the picrate, and certain complex salts coprecipitate with corresponding salts of cesium.

In the application of tracer methods in biology, C^{14} and H^3 have a great number of uses. For many years before its radioactivity was detected (first by S. Ruben and M. D. Kamen, 1940) it was known that C^{14} is produced by the (n,p) reaction in nitrogen. Radioactivity of the product was difficult to detect since its half-life is long (5,568 yr.) and the maximum energy of the emitted beta particles is low (155 kev). Though the half-life of H^3 (tritium) is considerably shorter (12.26 yr.), the maximum energy of the beta particles is very much lower (18.1 kev). Production of H^3 by the (d,p) reaction in deuterium had been established in 1934; its radioactivity was not detected until 1939 (Alvarez and R. Cornog). Tritium may be produced in weighable amounts by the reaction $\text{Li}^6(n,\alpha)\text{H}^3$ in a nuclear reactor (*see* DEUTERIUM AND TRITIUM). Long-lived radioactive isotopes of carbon and hydrogen being thus available in quantity, the way is open to an unlimited variety of tracer studies in organic chemistry, in biochemistry, and in the biological sciences generally. There are difficulties in working with C^{14} and H^3 , particularly with the latter because its radiations are so easily absorbed (in a few millimetres of standard air equivalent thickness). But this may also be put to good advantage; uptake of H^3 -labeled material in tissue may be localized to within correspondingly fine limits (about 1 micron) by autoradiography. One complication remains in all tracer work with this isotope; hydrogen presents the extreme case in which the ratios of the masses of the individual isotopes differ widely from 1. Therefore the chemical indistinguishability of the isotopes (particularly of H^1 and H^3) cannot lightly be taken for granted without further inquiry.

The archaeological use of C^{14} in radiocarbon dating has been briefly mentioned earlier. For other applications *see* RADIATION: BIOLOGICAL EFFECTS; RADIOLOGY; NONDESTRUCTIVE TESTING; ELECTRIC POWER; SUBMARINE.

RADIO ASTRONOMY, a branch of astronomical science, has contributed fundamental information on a variety of classical astronomical problems: the statistics of meteors, the distance of the sun from the earth, the surface temperatures of planets, the structure of the outer envelope of the quiet sun, and the spiral structure of our galaxy. It has also given insight into new problems and phenomena such as the nature of bursts and flares on the sun and their relation to such terrestrial phenomena as auroral and geomagnetic activity. Radio astronomy has suggested valuable clues to the origin of cosmic rays and their acceleration in a vast halo of ionized gas surrounding our galaxy. The astrophysical importance of nonthermal processes in nature and the apparent omnipresence of large-scale magnetic fields have been recognized for the first time. Ultimately, as new equipment is developed, radio astronomy may help solve fundamental cosmological problems.

History.—In 1931 a Bell Telephone Co. engineer, Karl G. Jansky, was investigating atmospheric radio-frequency disturbances that might hinder transoceanic telephone service. Although some disturbances were caused by local or even remote thunderstorms, there was a third source of noise, apparently of extraterrestrial origin. Jansky showed that this radiation resembled noise generated in metallic conductors and attributed this cosmic "static" to interaction between electrons and ions in interstellar space. Also in the U.S., Grote Reber, with the aid of modest equipment, was able to demonstrate that the origin of cosmic radio-frequency radiation was not confined to the region of the galactic centre but was spread along the galactic plane with a strong secondary maximum in the constellation Cygnus. Radio observations of the sun and of its transient phenomena were started in the early 1940s.

After 1945 a combination of technological advances, ingenious ideas, and adequate support led to spectacular developments. Large antennae, both fixed and movable, and interferometers enabled fainter sources to be observed and with higher resolution. The sensitivities of receivers were improved enormously with the development of masers (*q.v.*) and parametric amplifiers. Modern data-processing techniques permitted rapid assessment of observations. For further information on this aspect of radio astronomy, see **TELESCOPE, RADIO**.

Advantages and Limitations of Radio-Frequency Studies.—Besides the obvious advantage of examining celestial objects in an entirely different frequency range, radio astronomy offers other opportunities. Radio waves penetrate the smog and dust of interstellar space and also the clouds of a planetary atmosphere. Thus, astronomers can obtain a view of the central regions of our galaxy unhindered by the obscuring clouds of small particles that restrict optical observations. Likewise, they can study the surface of Venus either by the thermal radiation it emits or from the reflection of radar waves.

There is, however, one basic limitation in the radio-frequency technique which somewhat limits its usefulness for certain problems: the lack of angular resolution. Whereas the wavelength of visible light is very small compared with the aperture of the telescope, the wavelength of the radio-frequency radiation is often comparable to or even larger than the aperture of the radio telescope. The resolving power, *i.e.*, the ability to distinguish two objects separated by a small angular distance d , depends on the ratio of the wavelength λ to the aperture D ($d = 1.2\lambda/D$). For a 60-in. telescope and a wavelength of 5×10^{-5} cm. (an average for visible light), $d = 4 \times 10^{-7}$ radians or 0.08 sec.

With a 60-ft. dish and 21-cm. radiation, the angular resolution is 1.38×10^{-2} radians or about 0.8° ; *i.e.*, somewhat larger than

the angular diameter of the moon or sun. With the wavelengths ordinarily employed, most radio telescopes have resolving powers considerably less than that of the human eye. Accordingly, interferometric techniques are applied much oftener than in optical astronomy.

Very high resolution in frequency can be obtained. The profile of the 21-cm. line of neutral hydrogen gas can be studied to yield important information on the motion of the gas and its temperature.

The range of wavelength over which observations can be secured also must be considered. The long wavelength limit is between 15 and 30 m. It is fixed by the degree of ionization of the ionosphere. The upper limit of the wavelength is fixed by the condition that a radio wave can travel through an ionized gas only as long as its frequency is greater than a critical frequency ν_c , in megacycles (Mc.) per second, given by

$$\nu_c^2 = 8.06 \times 10^{-6} N_e \quad (1)$$

where N_e is the number of electrons per cubic centimetre. Radio waves of frequencies less than ν_c are reflected by the ionosphere. Since the degree of ionospheric ionization, *i.e.*, the number of electrons per cubic centimetre, depends on the solar radiation in the far ultraviolet, ν_c will vary from time to time. The atmosphere is opaque for wavelengths shorter than 1.5 mm. There are strong absorptions at 2.5 mm., 5 mm., and 1.34 cm. The transparency at 8.5 mm. is better than the sky in the optical regions. At the high-frequency end of the spectrum the radio astronomer begins to be hampered by nuisances, such as rain, that also plague optical astronomers. Thus, radio astronomy, as well as optical astronomy, can benefit from experiments conducted in space. Low-frequency cosmic radio radiation, which is extinguished in the earth's ionosphere, can be studied with detectors carried by rockets or satellites. High-frequency radiation between the far infrared and the microwave region can be studied only from space.

Sources of Radio-Frequency Radiation.—Three important types of cosmic radiation are studied by the radio astronomer: (1) thermal radiation; (2) 21-cm. radiation of hydrogen; and (3) non-thermal radiation. Each of these types has its own distinctive characteristics; by studying radiation from a source at different frequencies it is possible to distinguish between types (1) and (3).

Thermal radiation in the radio-frequency region is emitted by any heated body in accordance with the usual laws for the emission of radiation. (See **HEAT: Radiation**.) The surface brightness of a source (not necessarily a thermal emitter) can be expressed in terms of the temperature T of a black body (*q.v.*) that would give the same intensity of thermal radio noise. Also a black-body source can be used to calibrate the receiver.

Radio-frequency radiation received from extraterrestrial sources has the character of random noise superposed on the background of thermal radiation from the surroundings. It is as though an ordinary telescope, its dome, and all terrestrial surroundings glowed brightly so that the astronomer had to measure sun and stars which appeared as objects only slightly brighter than their background. Hence the radio-frequency detection equipment has to discriminate between objects with radio-frequency surface brightness only slightly greater than those of their surroundings.

Differences corresponding to 0.05° K are measurable. If the angular size of the source is smaller than the "beam width" or resolution of the antenna, the measured "brightness temperature" T_b will be less than its true temperature (unless the object is superposed on a hotter source). Since the surface brightness declines as the wavelength increases, thermal sources can be measured best at high frequencies.

An incandescent gas in interstellar space is fully ionized; *i.e.*, the individual atoms are broken down into ions and electrons. Such a "plasma" may emit thermal radiation by the mechanism of what is called free-free emission. An electron (which is negatively charged) moving in the neighbourhood of a positive ion becomes accelerated, and as the electron speeds up it radiates energy. The electron remains free; *i.e.*, it is not captured by the ion. The amount of energy radiated depends on the temperature, frequency, and density of the gas. Such emission is observed in

our galaxy from large, glowing clouds of hydrogen such as the Orion nebula.

The 21-cm. radiation is produced by neutral hydrogen atoms. The proton and electron are held together by strong electrostatic forces. Both particles spin, and since they are electrically charged they behave like tiny magnets, so that in addition to electrostatic forces there are weak magnetic forces. When the atom is in its normal condition with the electron moving in the smallest orbit, two different energy states are possible: these correspond to the spinning electron and proton being lined up parallel, or antiparallel, to one another. A jump from the lower to the higher energy state may be produced when radio-frequency corresponding to a wavelength of 21 cm. impinges on the atom. Conversely, a "flip" of the electron spin, corresponding to a change from the higher to the lower energy state, causes the emission of 21-cm. radiation. In the early 1940s H. C. van de Hulst pointed out that such radiation should be emitted by clouds of cold hydrogen, and in 1951 this radiation was actually detected by two astronomers at Harvard.

The 21-cm. line is intrinsically "infinitely" sharp; the width of the line as observed in clouds of cold hydrogen in the Milky Way arises from the motions in the line of sight. Part of the widening is due to motions of individual radiating atoms, but most of it comes from large-scale differential motions of gas clouds caused by galactic rotation, "turbulence," and hydrodynamical streaming. Special multichannel receivers have been devised for 21-cm. work so that when a radio telescope is pointed to a hydrogen cloud the entire line profile can be observed at once.

Nonthermal radiation, which is of great importance in the radio-frequency range, is believed to originate mostly in two types of mechanism: plasma oscillations and synchrotron emission.

If the charges of opposite sign in an ionized gas are displaced with respect to one another, they will oscillate back and forth with a frequency given by equation (1) (see *Advantages and Limitations of Radio-Frequency Studies*, above). Thus the forced period of oscillation, or "plasma frequency," is determined entirely by the density of the ions in the gas.

Electrons accelerated to very high velocities (almost that of light) and placed in a magnetic field will emit polarized electromagnetic radiation in the same direction as they are moving. If a host of electrons of different energies are simultaneously thus accelerated, they will emit a continuous spectrum of radio-frequency radiation and even visible light if they are moving fast enough. Such radiation was first observed in a synchrotron and thus is called synchrotron radiation.

Radio-frequency emission interpreted as plasma oscillations and as synchrotron radiation is observed in active events in the sun, while synchrotron radiation is believed to be responsible for the bulk of the nonthermal emission observed in sources elsewhere.

Radar Astronomy.—Most radio astronomy work is of the "passive" type, concerning itself with measuring radiation emitted by a distant source and trying to secure the best data possible. In this respect it resembles optical astronomy. However, to nearby objects, such as meteors, the moon, and some terrestrial planets, it is possible to direct radar signals and obtain a reflection.

An important early application of radar was to the study of meteors. As a meteor passes through the rarefied upper atmosphere of the earth it ionizes a column of gas. A radio wave may be reflected from this column; from the intensity of the reflected beam, and because the intensity depends on the angle between the initial beam and the path of the meteor, it is possible to obtain the direction of the meteor and eventually its velocity. In this way, extensive data have been obtained on the orbits of meteors and meteor streams. The radar technique possesses one important advantage. Since the radar reflection depends only on the ionization of the air by the meteor, it can be applied during the day as well as during the night. Thus it has been possible to identify several daytime meteor streams that had not been previously observed. The radio observations also substantiated the more reliable optical observations in showing that the orbits of meteors are elliptical, rather than hyperbolic; i.e., meteors belong to the solar system.

Radar reflections from Venus have provided a precise method for establishing the scale of distances in the solar system. Orbit theory gives the relative positions and distances of all bodies in the solar system, but the scale can be fixed only when one particular distance (e.g., the distance from the earth to Venus) is found at one particular epoch. The problem is beset with great technical difficulties, not the least of which is that the strength of radar echoes decreases with the fourth power of the distance instead of with the square of the distance. Nevertheless, this difficult problem has been solved by groups in the United States, the United Kingdom, and the Soviet Union. The Lincoln Laboratory of the Massachusetts Institute of Technology found the astronomical unit (semi-major axis of the earth's orbit), or, more loosely, the distance from the earth to the sun, to be 92,955,750 (± 250) mi., while the Jet Propulsion Laboratory of the California Institute of Technology obtained a distance of 92,956,070 (± 160) mi. Although these distance determinations are much more precise than that found by E. K. Rabe, who used perturbation theory, they differ from his result by an amount that is intolerable. The problem requires further investigation.

The radar techniques yield other valuable dividends. They indicate that Venus is rotating slowly, perhaps in synchronism with its orbital motion but most likely backward. The reflection characteristics of the surface correspond to substances such as rocks or sand and not to water. Eventually, with larger dishes and improved techniques, Mars and Jupiter can also be detected.

Observations of Planets and the Moon.—Studies of the radio-frequency emission from the moon and radar investigations substantiate the conclusion that the moon's surface layers have good thermal insulating properties. Only a few inches beneath the surface the extremes of heat and cold between the lunar day and night are "smoothed" out and the temperature remains constant. The reflective properties resemble those of sand.

The sunward side of Mercury has a temperature of about 600° K (620° F), while Venus appears to have about the same surface temperature in spite of the fact that it is almost twice as far from the sun. Presumably, the atmosphere of Venus acts as a heat trap; both sunlit and dark sides are extremely hot. Although the planet's surface is hidden by clouds and optical measurements therefore could only apply to high levels in the atmosphere, radio observations seem able to establish temperature conditions at the surface quite accurately.

Radio observations of Mars show that its surface temperature is about the same as that anticipated from the optical observations. Studies of Jupiter indicate that it apparently emits three types of radio-frequency radiation. The first is the thermal radiation corresponding to its surface temperature, which is controlled by radiation from the sun. The planet also emits a nonthermal continuous radiation that is correlated with solar activity. Finally, there are "bursts" of low-frequency radiation, possibly due to high-energy particles that have been trapped in the planet's magnetosphere and occasionally leak to the atmosphere. Some writers have attributed the steady nonthermal radiation to synchrotron emission from the magnetosphere, which is believed to be extensive around this planet.

Solar Radio Observations.—Radio-frequency observations have contributed greatly to gaining an understanding of the outer envelopes of the sun. These are called the photosphere, chromosphere, and corona. The photosphere of the sun is the bright surface seen in white light, where radiation corresponds to a temperature of about 5,800° K. Its average density is low—less than 0.01 that of the sea-level atmosphere. Above this lies a very non-homogeneous filamentary structure called the chromosphere; during eclipses it appears as a bright red ring surrounding the moon. The outermost envelope, the corona, is about 1,000,000 times fainter than the sun and consists of gases with a temperature of about 1,000,000° K as measured by the speeds of ions and electrons. Optically, the corona can be studied only with great difficulty except during an eclipse, but in the radio-frequency region it can be studied at all times.

The equation for critical frequency shows that at the lower frequencies (longer wavelengths) radiation is obtained only from

an attenuated gas, whose density corresponds to that of the outer corona. As the receiver is tuned to higher frequencies it is possible to penetrate deeper and deeper into the corona and finally into the chromosphere. At the shortest wavelengths it is possible to reach to the optical photosphere. With proper interferometers it is possible to attain fairly high resolution and by combining observations from several days one may eliminate any effects caused by disturbed areas (which may occur even at times of sunspot minimum).

The radio emission from the quiet sun is of thermal origin; its intensity depends on the temperature of the radiating gas and on the total amount of material along the ray. By combining optical and radio data it is possible to construct a model of the chromosphere and corona that suffices for many purposes. Difficulties arise from the extremely nonhomogeneous nature of the chromosphere and the fact that the emitting gases are far from thermal equilibrium. Furthermore, the radio waves suffer pronounced refraction effects and the observations suffer from effects of low spatial resolution. Observations of the occultation of the Crab nebula show that the outer corona has a nonuniform structure. As the sun passes in front of this strong radio-frequency source, the latter's signal shows irregular fluctuations.

It is in studies of transient solar phenomena, particularly those connected with sunspots and flares, that radio astronomy has made its most dramatic contributions. Because the radio emission is produced in the solar corona in regions that cannot be observed in optical frequencies, radio-frequency data provide indispensable information on solar phenomena. Earlier work was done with receivers operating at single frequencies and antennae with low angular resolution. Outstanding "bursts" were often observed at times of solar flares but not until J. P. Wild's invention of the radio spectrograph were solar radio-frequency observations obtained in a form that permitted meaningful interpretations.

A radio spectrograph contains a tunable, narrow band-pass receiver capable of detecting signals over a broad frequency range. A mechanical device causes the detection frequency to sweep over its entire range twice per second. The signal is displayed on a cathode-ray tube, displacement being proportional to frequency, and intensity to signal strength. This tube is monitored with a motion-picture camera so that the record gives intensity as a function of frequency and time. The resultant display is called a dynamic spectrum.

Of the five types of bursts that are generally classified, four, which are associated with flares, are of particular interest. Types III and V appear to be associated; type IV is always connected with type II but the converse is not true.

In the "slow" drift type II bursts, the frequency slowly decreases with time. A fundamental and a first harmonic exist; furthermore, the emission is often doubled. Type II bursts have been interpreted as plasma oscillations. It is supposed that at the time of the flare a strong shock wave or hydromagnetic wave leaves the spot region and rushes into the corona where it produces oscillations. As the disturbance rises higher it excites oscillations in a gas of steadily declining density. Therefore, the frequency decreases. If a model of the corona (which gives electron density and temperature as a function of height) is available, it is possible to relate frequency and height and thus obtain the velocity of the disturbance. In this way velocities of the order of 500 km/sec were obtained if average coronal densities were assumed.

Fortunately, a check on this hypothesis is available. Wild and his associates developed an interferometer that enabled them to locate the position of the source of each frequency in the corona. Observations clearly demonstrated the increase of height with decrease of frequency but the disturbance seemed to move at about 1,000 km/sec along arcs of higher than average density.

Type II bursts are sometimes followed by type IV bursts, which display a continuous spectrum covering a wide range in frequency. P. Boisot, using an interferometer at Nancay, noted that the type IV emissions first appeared high in the corona and then extended out three or four solar radii before finally settling back into the sun after several hours. The broad range in frequencies of large angular size and long duration of the type IV bursts suggests

synchrotron radiation. Apparently what happens is that at the time of certain unusual flares, a "blast" generates a shock wave or hydromagnetic wave which travels through the corona and excites the plasma oscillations that generate the type II bursts. The plasma carried behind the shock front conveys a magnetic field with it, and charged particles, becoming accelerated to high energies in the twisted and warped field, produce synchrotron radiations.

All flares that produced cosmic rays and high-energy protons had type II bursts followed by type IV events. Likewise, aurorae and geomagnetic storms tend to be associated with type II plus type IV bursts. Evidently large pockets of ionized plasma carrying magnetic fields with them may be "blown" from the sun and engulf the earth.

The types III and V bursts somewhat resemble the II and IV bursts, respectively, except that type III bursts are characterized by short duration and a drift in frequency 200 times faster than that of type II bursts. The type III bursts are produced by a disturbance which moves out at about half the speed of light and produces plasma oscillations. Behind the shock front are more electrons which become accelerated in magnetic fields up to energies as high as 2 Mev or more and produce synchrotron radiation over a large radiating volume. These are the type V bursts.

The entire phenomena may be summarized somewhat as follows. Sunspots and associated magnetic regions are manifestations of the hydromagnetic phenomena in the sun. The coolness of the spot and the transient phenomena that occur in or near it all result from the existence of strong magnetic fields in the solar photosphere. The most spectacular of these phenomena are the flares that may be produced when magnetic energy is suddenly liberated. At such a time there occurs something akin to an explosion low in the solar atmosphere. Optically, this is seen as a sudden brightening of the red line of hydrogen. Blobs of fast electrons with velocities approaching that of light escape suddenly from the sun and cause type III and type V bursts. Also material is ejected at a slower velocity, carrying with it a magnetic field. These produce the types II and IV bursts and ultimately geomagnetic storms or even cosmic-ray enhancements.

Radio astronomy has provided valuable clues concerning the structure of the outer solar envelopes and the nature of transient phenomena such as flares. The importance of nonthermal radiation has been clearly demonstrated, and challenging theoretical problems have been proposed. Further improvements in instrumentation could help. Wild's radio-heliograph, designed to provide "moving pictures" of the sun at metre wavelengths, will enable scientists to separate thermal and nonthermal effects in the region of the outer corona.

Cosmic Radio Noise.—The first cosmic radio source detected was the central bulge of our galaxy. After developments of interferometers permitted a great improvement in resolution and as the sensitivity of receivers was improved, the amorphous galactic mass was resolved into a "fine structure" of smaller sources; likewise, a number of discrete sources distributed over the entire sky were recognized and catalogued.

At the highest frequencies, thermal sources are relatively brighter. These sources are clouds of ionized hydrogen (diffuse nebulae), and the emission is produced by the interaction of electrons and ions (free-free transitions). The dependence of emission on frequency is in agreement with theoretical predictions. The positions of many of them agree with diffuse nebulae observed in the optical region of the spectrum; others would be visible as diffuse nebulae were there no obscuring clouds to hide them. At the lowest frequencies, e.g., 20 Mc/sec, these ionized hydrogen regions appear in absorption against a bright background. At intermediate frequencies, e.g., 120 Mc/sec they are lost in the background. The Milky Way contains many nonthermal sources in addition to the thermal ones.

It is a point of considerable interest that the central bulge of the galaxy, the nonthermal galactic sources, and the discrete sources far from the galactic plane all show roughly the same type of radio spectrum—dependence of intensity on frequency. It is tempting to suggest that all these nonthermal sources are dependent on the same mechanism; i.e., synchrotron radiation.

The discrete sources were first regarded as radio "stars," but as the resolution of radio telescopes improved and the source positions could be accurately determined, it became evident that they could not be identified with optical stars and that they showed finite angular sizes. Such bright nonthermal sources that could be identified with optical objects turned out to be rather unusual nebulae. At the position of the bright Cassiopeia source, filaments of nebulosity in very rapid motion were found. These were interpreted as remnants of a supernova, largely dimmed by intervening clouds of absorbing material. Tycho Brahe's and Johannes Kepler's supernovae of 1572 and 1604, respectively, have now been identified by their radio-frequency emissions.

The radio source Taurus A was identified with the Crab nebula, which had been a supernova in 1054. Optically, this remarkable object shows an amorphous mass which emits a bright-line spectrum. Furthermore, the light of the amorphous mass is polarized, suggesting that it is produced by electrons moving with such high energy that they radiate in the visible as well as in the radio-frequency ranges. The enormous energies involved during the 900-year lifetime of this object present one of the most challenging problems for theoretical astrophysics.

Other optically identified galactic nonthermal discrete sources, such as IC 443 and the network nebula in Cygnus, appear to be defunct supernovae; therefore, it is generally believed that most of the discrete sources in the galaxy are of this type. The diffuse background radiation, presumably also of nonthermal origin, is believed to originate in a "halo" that surrounds the galactic system. Nonthermal halos are observed around nearby spiral extragalactic systems such as M31. Presumably, an attenuated cloud of gas is held in place by a weak magnetic field. In this region particles can be accelerated to very high energies by the Fermi mechanism (see COSMIC RAYS). Evidently, high-energy particles (low-energy cosmic rays) can be produced by supernovae or even stars like the sun. They are accelerated to higher energies by collisions with magnetic fields in the galaxy, presumably mostly in the halo. At the same time the accelerated electrons produce synchrotron radiation which is detected by radio telescopes as a faint radio-frequency "glow" over the entire sky.

External galaxies fall into two classes: the normal type, in which the ratio of radio emission to optical brightness is roughly constant; and the abnormal type, which are strong radio emitters. Some elliptical galaxies are poor radio emitters but spiral and irregular galaxies appear to have vast radio coronas. For example, the radio (halo) diameter of M31 is almost three times that of the optically detected diameter.

Galaxies that radiate much more intensely than normal systems in the radio-frequency range are called radio galaxies. An object such as the giant elliptical M87 in Virgo radiates a thousand times as much radio-frequency energy as does our galaxy. This particular system contains a peculiar "jet," the like of which is not found in any other galaxy. It is probable that many of the faint galaxies detected in the surveys are of this type; there is no chance of ever observing them optically.

A source of this type identified with what appeared to be a pair of colliding galaxies in Cygnus led to the suggestion that the emission was due to very hot gases, heated by the collision. Other radio galaxies could not be so interpreted. In fact, interferometer measurements show that for certain optically identified radio galaxies the source of radio emission was centred not on the optical image but was located in two invisible "blobs" on either side of it. Thus the radio galaxies would appear to possess not halos of the "ordinary" type but appendages of an intrinsically different sort, whose origin and structure are not at all understood.

The most dramatic phenomena discovered by radio astronomy are the quasi-stellar objects, starlike optical and radio-frequency emitters at enormous distances from the earth. (See QUASI-STELLAR RADIO SOURCES.)

The 21-cm. Radiation.—The 21-cm. line has proven to be one of the most useful tools for studying spiral structure and the distribution and mass of cold hydrogen in this and nearby galaxies. From the peak intensity of the 21-cm. profile it is possible to deduce the temperature of the hydrogen, normally

about 100° K, and from the shape of the profile and its displacement from its zero-velocity position the motions in the line of sight may be determined. By observing profiles in different galactic longitudes and by making the assumption that the gas is moving in circular orbits, one can attempt to derive the positions of the spiral arms. The analysis is difficult because the material is not uniformly spread along the spiral arms, appears to have "turbulent" motions of its own, and may be moving outward along the arms, at least near the centre. Since the distance of any particular cloud of neutral hydrogen cannot be ascertained from radio data (only its line-of-sight velocity can be measured), interpretations are often difficult. Observations of other spiral systems, notably M31, are helpful in suggesting clues. The total mass of neutral hydrogen can be measured roughly as a function of distance from the galactic centre. It is found, for example, that in great nebulous complexes such as Orion or 30 Doradus, the luminous nebula contains but a small fraction of the total mass. The rest resides in vast surrounding clouds of cold hydrogen. The Orion complex is estimated to contain 50,000 solar masses; that of 30 Doradus is even more extensive. In 1963 the hydroxyl (OH) ion was detected for the first time in interstellar space by analyzing the profile of the 21-cm. line.

Future Outlook.—Impressive contributions by radio astronomy have wrought profound changes in our understanding of solar phenomena, the galaxy, and physical processes in interstellar space. However, correlation of optical and radio cosmic phenomena, interpretations of diffuse nebulae, etc., have been retarded because of inadequate support for ground-based optical astronomy. Since 1945 only two major optical telescopes have been planned and built in the U.S., the 120-in. reflector at Lick Observatory on Mt. Hamilton, Calif., and the 85-in. reflector at the Kitt Peak National Observatory in Tucson, Ariz. Most observatories are equipped with archaic (1862–1910) or very small optical telescopes which are almost worthless for following up the leads suggested by radio astronomy investigators.

A serious menace to radio astronomy looms ahead. As communications satellites are developed, less and less of the radio-frequency spectrum will be available for astronomical research. Just as many optical observatories have been "submerged" below the illuminated sky of a growing metropolis, so may all radio observatories be made useless by a sky filled with communications satellites, reflecting needles, etc., jamming so many frequencies with sidebands and harmonics that little cosmic radio noise will be able to get through.

RADIO BEACONS, radio transmitting stations that provide navigational aid to ships and aircraft. Situated in a fixed geographic location, a radio beacon emits a distinctive identifying code. Thus, a navigator on a ship or airplane is able to recognize signals from one or more known locations; this information helps him to determine the bearing, location, and course of his own craft. Radio beacons are sometimes called radiophones and aerophares. See NAVIGATION: *Electronic Aids Common to Marine and Air Navigation*.

RADIOCARBON DATING. Radiocarbon age dating, developed in the late 1940s at The University of Chicago, is an example of the application of one of the newest sciences (atomic energy) to one of the oldest (archaeology). The technique involves measuring the relative activities of radioactive carbon (C^{14}) in (1) present-day living organic matter and (2) the sample under investigation, and multiplying the logarithm of this ratio by the rate at which the activity of C^{14} decays with time. Careful measurements have shown that the activity of any given preparation of carbon-14 is reduced by exactly one-half during each interval of $5,568 \pm 30$ years. This value is called the half life of C^{14} .

Radiocarbon is produced in nature by an indirect process in-

SAMPLES OF OBJECTS OF KNOWN AGE DATED BY RADIOCARBON METHOD

The curve is calculated from the assay for modern wood and the laboratory measurement of the half-life of radiocarbon ($5,568 \pm 30$ years). The individual points show the specific radioactivities of the various samples of known age (the latter given in parentheses). The age of the sample as estimated by the radiocarbon method is shown by the point on the curve corresponding to the indicated specific radioactivity. The range in specific radioactivity for a given sample is the standard deviation based solely on the number of counts taken; it does not include other errors, such as those arising from contamination.

volving the interaction of cosmic rays from outer space with the nitrogen in the earth's atmosphere. The competing processes of formation and of decay of C^{14} have been going on for so long that the equilibrium has been established, and the world inventory of C^{14} is estimated at about 70 metric tons. Radiocarbon therefore has been introduced into the biosphere, and all living matter contains a small quantity of radiocarbon which averages 15.3 ± 0.1 disintegrations per minute per gram of contained carbon. This activity remains constant throughout the life of the organic matter because of the above-mentioned equilibrium processes.

However, at death the introduction of radiocarbon into the specimen ceases, while the normal decay of the contained radiocarbon continues according to the half-life mentioned above. Therefore an archaeological specimen (for example, a mummy or a tree) which yields 7.65 disintegrations per minute per gram of carbon instead of 15.3 is judged to be $5,568 \pm 30$ years old. If the material shows only one-fourth the radiocarbon content of living matter, the age of the specimen is $11,136 \pm 60$ years, etc.

Age dating has revealed that there lived in North America over 9,000 years ago people who were capable of performing the finest basketry work; that the continents of North America and Europe were both glaciated in their northern latitudes 11,000 years ago; and that the calendars of the ancient Babylonians and the Mayas can be correlated with that of the Christians. The accompanying graph indicates the correlation obtained between the ages of various samples as determined by radiocarbon dating and by conventional methods.

Refinements in the technique of measurement have been made by reducing, as far as possible, the effects of spurious radiation, including background activity due to cosmic radiation, and radioactive impurities in the shielding of counters and in the materials of construction of the counter itself. These refinements permit the extension of radiocarbon dating to samples which could be as much as 50,000 years old. Laboratories at research institutions

scattered throughout the world are cooperating in dating archaeological specimens by this method.

RADIO COMPASS, a radio receiving set which permits determination of the line of travel of waves as received from transmitting stations. See NAVIGATION; RADIO.

RADIOLOGY is the branch of medicine that deals with the employment of X-rays as an aid in the diagnosis of disease and the use of X-rays, gamma rays and other forms of ionizing radiation in the treatment of disease. For details of the physical nature, method of production and technical and industrial applications of the various components of the electromagnetic spectrum, see RADIOACTIVITY and X RAYS.

This article is organized as follows:

I. Diagnostic Radiology

A. Apparatus

1. Quality and Intensity of Radiation Employed
2. X-Ray Generators
3. X-Ray Tubes
4. Films, Screens and Cassettes
5. Grids
6. Fluoroscope

B. Techniques

1. Timing the Exposure
2. Processing X-Ray Films
3. Stereoscopic X-Ray Filming
4. Contrast Media
5. Fluoroscopy

C. Applications

1. Teeth
2. Bones
3. Chest and Heart
4. Skull, Brain and Spinal Cord
5. Gall Bladder and Bile Ducts
6. Urinary Tract
7. Female Reproductive Tract
8. Blood Vessels
9. Stomach and Intestine

II. Therapeutic Radiology

A. Dosage

1. Measurement
2. Low-Voltage X-Rays
3. Medium-Voltage X-Rays
4. Radium
5. Artificial Radioisotopes

B. Radiation Physics

C. Clinical Aspects

I. DIAGNOSTIC RADIOLOGY

A. APPARATUS

1. Quality and Intensity of Radiation Employed.—Concern with the various implications of thermonuclear weapons has stirred up a largely unwarranted fear of possible risk from even such small tissue doses as those delivered in X-ray diagnosis. Of course, it is unwise to employ diagnostic radiology (or, for that matter, drugs or surgery) unless there is real need for it. When there is such need, X-ray examinations conducted by qualified radiologists involve risks smaller than those encountered every day at home, at work and on the street, and smaller than the risk of getting along without needed examinations, especially when these may reveal a serious disorder.

In some of the work for which X-rays are used, the quality or penetrating ability of the radiation is expressed in wave length, in frequency or in terms of its absorptivity in filters of standard composition and thickness; and its intensity is designated in ionization units, such as the roentgen. In X-ray diagnosis, however, it is the practice to indicate radiation quality and intensity by stating the voltage and current applied to the tube, the current being expressed in milliamperes, abbreviated ma. ($1 \text{ ma.} = 0.001 \text{ amp.}$), and the voltage in peak kilovolts, abbreviated kv. Current is measured by means of a milliammeter inserted between the two halves of the secondary winding of the X-ray transformer at a point where the potential is close to zero; and tube voltage is measured by means of a kilovoltmeter wired across the primary of the X-ray transformer.

Certain aspects of alternating currents and of pulsating unidirectional currents will be reviewed at this point. When the instantaneous voltage of the current produced by a single-phase, 60-cycle, alternating-current generator is plotted on a time scale, a sine curve is observed. Rising from zero, voltage reaches full potential during the first $\frac{1}{240}$ sec., returns to zero by $\frac{1}{120}$ sec., falls to full negative value by $\frac{1}{60}$ sec. and returns to zero by $\frac{1}{30}$ sec., repeating the pattern indefinitely. That portion of the curve lying between the first and third zero points is called one cycle, and it is the repetition of this cycle 60 times in each second that gives 60-cycle current its name. Obviously the designation of the voltage of such a current requires reference to the factor of time, and for such applications as heating, lighting and power the "root mean square" value is employed. This is abbreviated R.M.S. and means the square root of the mean of the instantaneous voltages throughout the entire cycle.

A time-voltage plot of the potential applied to the tube of a self-rectified X-ray machine consists of a distorted sine curve in which the peak of the half cycle that is used is lower than that of the half cycle that is suppressed; and in the case of full-wave rectification the plot becomes a series of more or less distorted half cycles, all having the same electrical sign.

In pure sine wave alternating current, R.M.S. voltage may be computed from maximum instantaneous voltage (MIV) or vice versa by substitution in the equation

$$\text{R.M.S.V} = \frac{\text{MIV}}{\sqrt{2}}$$

but in pulsating unidirectional currents this simple relationship breaks down. The R.M.S. values for such nonsinusoidal currents could be determined by suitably designed meters or by complete analysis of the instantaneous voltages throughout the curve, but this is not commonly done because in the production of X-rays it is the maximum instantaneous voltage of the current passing through the tube that is of particular importance. This voltage is termed the peak voltage, and since in practice it amounts to several thousands of volts it is commonly expressed in kilovolts (1,000 v. = 1 kv.). In most X-ray generators the so-called kilovoltmeter is merely an ordinary A.C. voltmeter wired across the primary winding of the high-tension transformer but calibrated in peak kilovolts by means of direct sphere gap measurements of tube voltage made by the manufacturer during the factory calibration of the machine.

For fluoroscopy and the making of X-ray films, tube current may be as low as 3 ma. or as high as 500 ma. or even higher, and voltage usually ranges from 45 kv. to 90 kv. or even up to 130 kv. The magnitude of the voltage applied to an X-ray tube has two important effects on the radiation that is produced. It determines the wave-length composition of the beam and therefore its penetrating ability, and in addition affects the intensity of all beam components exponentially. For example, a tube voltage of 45 kv. will produce a certain amount of rather soft radiation having a maximum shortness of approximately 0.274 angstroms (Å) (0.274×10^{-8} cm.), a type of radiation so feebly penetrating that it is unsuitable for the fluoroscopy or filming of heavy body parts. Doubling the voltage (to 90 kv.) brings the maximum shortness of the beam down to 0.137 Å, thus providing penetration adequate for the thickest anatomical parts, and in addition this voltage change quadruples the intensity of all the components of the beam.

Contrary to a widely held misconception, there is no specific relationship between the part to be examined and the voltage, current and exposure time that should be employed. Over a considerable range, these factors—voltage, current and exposure time—may be juggled almost at will, provided only that the time intensity product of the radiation reaching the film approaches a constant that has been determined empirically as adequate for recording the tissue densities of the body part that is being examined. The experienced radiologist or X-ray technician uses voltages of approximately 60 kv. and currents of about 25 ma. for thin body parts that can be well immobilized, thus keeping the exposure time within the range where minor time switch errors are of negligible importance and allowing the use of fine-focus tubes;

but when the work to be done requires that the exposure time be as short as possible, he sets the time switch for $\frac{1}{60}$ sec. or sometimes even $\frac{1}{120}$ sec., sets the current at the maximum allowable for the tube (for example, 500 ma.) and then adapts to variation in the thickness and density of body parts by varying voltage.

2. X-Ray Generators.—In their simplest form the X-ray generators used in diagnosis consist of a hot-cathode X-ray tube, a controllable means of heating the cathode, a source of alternating current and a means of regulating the voltage of that current. Circuits of this sort are known as self-rectified because in them the X-ray tube itself acts as a rectifier, passing one half cycle and suppressing the other half cycle of the raw alternating current that is supplied by the transformer. Thousands of sets of this design are in daily use throughout the world, functioning as dental X-ray machines, portable and bedside X-ray machines and in small fluoroscopes. They are adequate where the service is intermittent and the loads range from 3 ma. to 10 ma. at potentials from 40 kv. to 75 kv., but for heavy work full-wave rectification is preferable.

In theory, full-wave-rectified generators differ from the self-rectified sets described above merely by the insertion of four electronic or solid-state rectifiers between the high-voltage terminals of the transformer and the terminals of the X-ray tube. In practice, however, they are much more complex, including voltage stabilizers for the filament of the X-ray tube, voltage regulators for the primary windings of the high-voltage transformer and the X-ray filament transformer, devices for the automatic selection and limitation of tube voltage and current, circuits for energizing the rotors of rotating anode tubes, meters, fuses, circuit breakers and some means for the precise timing of both short and long exposures. In addition, they allow employment of higher voltages and larger tube currents. All modern generators are completely insulated or "shockproof," regardless of whether they are of the self-rectified or the valve-tube-rectified type.

By the mid-1960s American radiologists were beginning to employ three-phase X-ray generators rather than the single-phase variety, particularly for the heavy loads and short exposures required in angiography. This practice had been well established in Europe more than a decade earlier. Such machines are expensive and complicated but the best of them provide a practically "ripple free" high-voltage output which makes for X-ray beams of maximum intensity for a given degree of punishment of the target of an X-ray tube.

3. X-Ray Tubes.—The tubes used in X-ray diagnosis consist of a well-exhausted glass-enveloped diode surrounded by a metallic housing that is lined with lead except at a small port through which the useful beam of X-rays emerges. The space between glass insert and housing is filled with insulating oil. In the simplest and smallest sets the tube housing is integral with the transformer housing, but in larger machines the two usually are separate, tube and transformer being connected by means of flexible, shielded, insulating cables. In these modern descendants of William David Coolidge's hot-cathode tube, the cathode stream is focused as a ribbon on a steeply inclined target so that the heat of impact will be distributed as widely as possible and yet the optically effective source of the rays will approach a point. Frequently two filaments are provided—one focusing the electrons sharply for use when great detail is required and small currents are allowable, the other distributing the electrons over a larger target area for use when heavier currents must be employed. Targets are of two general types—those that are stationary and those that rotate or spin during operation. In the stationary anode tube, the target is of swaged tungsten embedded in a massive copper anode which extends out through the glass envelope to conduct the heat of electron bombardment into the insulating oil that surrounds the tube. Sometimes there is a pump or impeller to circulate the oil, and usually there is a blower to expedite removal of heat from the housing.

Rotating anodes turn on precision bearings that are mounted within the exhausted glass envelope and therefore must be devoid of ordinary lubricants which would ruin the vacuum. The stator lies outside the envelope, its lines of force passing through the

glass to operate the rotor which is attached to the anode stem. Sometimes the anode disk is of massive copper with an embedded belt of tungsten to receive the electron bombardment, but more commonly it is of solid tungsten capable of withstanding a cherry-red heat during heavy loading. For many applications rotating anode tubes are extremely satisfactory, but they have the serious limitations of dissipating target heat almost exclusively by radiation through the glass envelope and lacking the direct conduction through copper that is so effective in the case of stationary anode tubes.

4. Films, Screens and Cassettes.—X-ray films consist of an acetate cellulose base coated on both sides with an emulsion of silver halide and gelatin. It is possible to prepare emulsions that are particularly sensitive to X-rays, but since most X-ray films are used in conjunction with calcium tungstate intensifying screens, the emulsions are given maximum sensitivity to the fluorescence of calcium tungstate rather than to X-rays themselves.

For the examination of certain parts—such as the teeth, fingers and toes—plain film without screens is ordinarily used, and in such applications it suffices to wrap the film or otherwise enclose it in a covering such as black paper or cardboard which is opaque to visible light but not to X-rays. For the filming of heavier parts, however, the exposure time can be reduced and the contrast in the image enhanced if films pressed between two intensifying screens are used instead of plain films. These screens must be in intimate contact with the emulsions if sharp detail is to be recorded. Such contact is provided by rigid lightproof containers known as cassettes. The fronts of cassettes are made of bakelite or magnesium to exclude light but admit X-rays, and when phototiming is employed the backs also must be reasonably radiotranslucent. The screen attached to the inside of the cassette front frequently is thin because it must transmit most of the radiation, but the rear screen is thick, absorbs more radiation and fluoresces more actively.

In the making of a film—for example, of the chest—the patient stands facing a 14-in. \times 17-in. duplitized X-ray film (double emulsion) contained in a double-screen cassette of the sort described above, the X-ray tube being arranged so that its beam of radiation passes through the patient's back in a direction perpendicular to the surface of the film. The X-rays induce a moderately brilliant fluorescent image of the lungs, ribs, heart, etc., on the front screen, produce a slight photographic effect directly on the front and rear layers of film emulsion, and finally induce a brilliant fluorescent image on the rear screen. The light from the two fluorescent images photographs itself onto the emulsion along with the two direct X-ray images, and in the completed film all four images, being superimposed, appear as one.

5. Grids.—X-rays arise on the target of an X-ray tube at the point where it is bombarded by electrons emitted by the cathode. In fine-focus tubes the effective X-ray source may have a diameter as small as 0.3 mm. and in coarse-focus tubes as large as 4.5 mm. All else being equal, X-ray images are sharpest in detail when the radiation source approaches a point and become blurred when the source is large. In the discussion that follows, a point source of radiation will be assumed, for convenience.

From their point of origin X-rays are propagated in straight lines in all directions over a solid angle of 4π , but most of them are absorbed in the lead lining of the housing and the cone of useful radiation that emerges through the port has an apex angle of only approximately 15° . Within the ordinary meaning of the terms, X-rays cannot be reflected or refracted by the substances they encounter on their straight-line course to the X-ray film, but some of them do become scattered. For small, thin parts, scattering is practically negligible, but for heavy parts, such as the skull and trunk of an adult, the radiation that is scattered in the patient's body fogs the image formed by the straight-line or primary radiation to such a degree that finer details become indistinguishable.

Prior to 1917 good X-ray plates of the skull, spine, hip, etc., required that the primary beam be narrowed to a very small diameter to reduce scattering, and 14-in. \times 17-in. plates of the entire pelvis of a heavy subject were so badly fogged by scattered radiation

as to be of little clinical usefulness (glass plates were used in those days rather than films). However, as early as 1912 Gustav Bucky in Germany laid the groundwork for overcoming this difficulty, and by the early 1920s there became commercially available, first in the U.S. and later in Europe, moving grids designed by the U.S. radiologist Hollis Potter. These instruments, known as Potter-Bucky grids or, less properly, as Potter-Bucky diaphragms, became an indispensable part of the equipment of all diagnostic radiologists. Such grids, consisting of an assembly of lead strips interspaced with strips of wood, plastic or other radiotranslucent material, are interposed between patient and film and are kept in motion while the exposure is being made. The lead strips are aligned as radii of a segment of a theoretical cylinder that has a diameter equal to twice the target-film distance. A small portion of the primary or unscattered radiation that emerges from the patient's body impinges squarely on the edges of the lead strips, where it is absorbed, but most of it passes through the interstices between the strips and thus to the film. The scattered radiation, on the other hand, being no longer aligned with the translucent interstices, impinges for the most part on the sides of the lead strips, where it is absorbed.

In Bucky's original stationary grids, the metallic members were thick and widely spaced, thereby causing disturbing patterns on the film, and Potter's contribution was to conceive and build grids that could be moved during exposure, thus obliterating the pattern of their grid members but not interfering with their ability to absorb scattered radiation. Modern moving grids are flat rather than curved; they are built to extremely precise dimensional tolerances, have great ability to absorb scattered radiation, and reciprocate throughout the exposure instead of starting before the exposure begins and continuing to move in the same direction until the exposure has been completed. Stationary grids were improved even more. In their original form they were virtually useless except as precursors to a great idea, but the work of the Swedish radiologist Eric Lysholm revived interest in them. Excellent European and U.S. units became available, some composed of parallel strips, others having two systems of parallel strips aligned at right angles to one another to form crisscross or honeycomb grids.

Grids of this latter type came to be used widely for bedside raying, raying in the operating room, for angiography and for spot filming of the stomach and intestines. In a type of moving grid developed later, transverse members are aligned at less than 90° to the longitudinal members; this retains most of the advantages of honeycomb grids and yet makes it possible to move the grid assembly during exposure and thus leave no pattern of it on the film.

Unlike the moving grids, the stationary ones inevitably leave their own images on films along with the images of the body parts that are being examined. In modern stationary grids, however, these superimposed patterns are regular and faint, detracting little from appearance and nothing from clinical usefulness.

6. Fluoroscope.—In its simplest form a fluoroscope is an apparatus for the direct observation of body tissues by means of X-rays. It consists of a fluoroscopic screen supported in front of the port of an X-ray tube so that a patient may be interposed between the screen and the source of the radiation. A shutter usually is provided to control the area of the beam of radiation emitted by the tube, and a sheet of plywood or other strong but radiolucent material is interposed between tube and patient to provide a surface on which the patient lies when the instrument is tilted from the vertical into the horizontal position. Many crystalline substances will glow when exposed to X-rays. Among the best for clinical fluoroscopy is zinc cadmium sulfide mixed with traces of other materials. A fluoroscopic screen consists of a piece of cardboard coated with a layer of such fluorescent salts and faced with a sheet of thick lead-bearing plate glass that is highly opaque to X-rays but almost perfectly transparent to the greenish light given off by the fluorescing crystals. Useful as it was for more than 50 years, the simplest fluoroscope has been rendered obsolete by the application of television circuits to the output of a Coltman-type image amplifier (see *Fluoroscopy* below).

B. TECHNIQUES

1. Timing the Exposure.—When the intensity of the X-ray beam is low and the exposure time of the order of ten seconds, errors of plus or minus a few tenths of a second are negligible and the simplest of spring-driven time switches are adequate to time the exposure; but for tube currents of from 100 ma. to 500 ma. and exposure times of the order of $\frac{1}{80}$ sec., precise timing becomes important and difficult, much of the difficulty being inherent in the pulsating nature of the current applied to the X-ray tube. When 60-cycle current is employed, X-rays are emitted by the target not continuously but in brief bursts starting from zero, rising to full intensity and then returning to zero every $\frac{1}{120}$ sec. (each half cycle). Brief exposures therefore must be measured out in half cycles, and it is important that the exposures be initiated and terminated approximately at zero points on the voltage wave. In other words, the timing device and the contactor must be phased with the generator. Such phasing formerly was accomplished reasonably well even with heavy conventional magnetic contactors, but it was rendered easier and more precise by the substitution of the electron discharge in heavy-duty thyatron for mechanically operated metal-to-metal contacts. The delivering of very brief high-current X-ray exposures has been rendered more precise by the use of three-phase rather than single-phase machines.

In the early 1940s it became possible to time X-ray exposures automatically by means of multiplier phototubes. Phototiming, as it is called, gradually was made available in commercial X-ray machines. In general radiography the phototube and a fluorescent screen are mounted in a box that is impervious to light but has a top that is transparent to X-rays. This box, known as a detector, is located beneath the Potter-Bucky grid where it receives radiation that has passed through the patient's body, the film and the cassette. The detector is calibrated empirically so that when the film has received an amount of exposure that will assure an optimum image, the phototube will have received sufficient fluorescent light to cause it to trigger an electronic switch and thus terminate the X-ray exposure. In photofluorography (described below) the phototube is mounted in the camera head and, like the lens, "observes" the fluorescent screen. In the case of the filming fluoroscope, which is so important in the examination of the gastrointestinal tract, the phototube scans an image produced on the fluoroscopic screen by radiation that has passed through the patient's body and through the back of the film cassette. Instead of a phototube and fluorescent screen some manufacturers employ a specially designed ionization chamber as a detector.

2. Processing X-Ray Films.—When the technician who exposes an X-ray film also develops it, the composition and temperature of the developer and the length of development need not be regulated precisely because modern films have wide latitude and the experienced worker learns to shorten or prolong development until inspection before a safelight indicates that an acceptable image has been obtained. Where the volume of work requires division of labour, however, the situation is different. One set of workers exposes the films to carefully measured amounts of radiation, and another group working in darkrooms develops them in solutions of standard strength and temperature for standard periods of time. Automatic film-processing machines found wide acceptance in the years after World War II. A decade later such automatic film-processing machines had become so much smaller, more dependable and less expensive that it seemed possible they would replace hand processing even in the smallest X-ray laboratories.

E. H. Land's Polaroid system of self-processing film holds obvious potential advantages for radiology, for example for films made in the operating room. At first the film was so slow that excessively long exposures were required, but by the mid-1960s film speed had been enhanced to the point where the best experimental Polaroid packets required less exposure than X-ray films with double screens. These packets are expensive and leave something to be desired in quality of image, but they are adequate in both respects for those situations where prompt availability of the finished film is of paramount importance.

3. Stereoscopic X-Ray Filming.—Three-dimensional vision is helpful in the radiography of any part of the body and is almost essential in X-ray examinations of the skull and trunk. The two films that are required for stereoscopic filming are made with the film and body part in identical spatial relationship for each but with the X-ray tube shifted slightly between the two exposures. The amount of the shift is determined by the relationship between the distance from the film to the target of the X-ray tube at the time the exposure is made and the optical distance from the film to the eyes of the observer at the time the two films are examined. If these two distances are identical the tube shift should be 66 mm., which is the average interpupillary distance, but if the commoner situation obtains and target-film distance is greater than film-eye distance, then the tube shift must be increased proportionally.

Even without the aid of instruments some workers become able to view one of the films with one eye, the other with the other eye, and then fuse these two slightly dissimilar, real, flat images into a single, virtual, three-dimensional image. It is more convenient, however, and for some persons actually essential to employ a special viewing apparatus.

4. Contrast Media.—The lungs show in X-ray films and in fluoroscopic images by virtue of the sharp difference between the X-ray absorbing power of the air that distends them and that of the pulmonary tissue itself. This difference in absorbing power is called "contrast." The heart, being composed largely of muscle and blood, contrasts strongly with the air-filled lungs adjacent to it but scarcely at all with the liver beneath; bones are distinguished from surrounding muscle and the various parts of bone from one another by virtue of the calcium phosphate they contain. To a great extent, however, the clinical usefulness of the X-ray examination depends on the employment of artificial contrast media. The most extensively used opaque medium is barium sulfate. Stirred into water and flavoured with a little chocolate sirup, this insoluble heavy metal salt is employed for examination of the esophagus and stomach; mixed with powdered resins and water it becomes a barium enema for the examination of the rectum, colon and terminal ileum. Iodized organic compounds are used for examination of the gall bladder, urinary tract, blood vessels, spleen, liver and bile ducts. X-ray visualization of the bronchi better than that obtained merely by the contrast of contained air is made possible by the introduction into the bronchial tree of unsaturated vegetable oil partially saturated with iodine. An emulsion of ethyl iodophenylundecylate also is used in bronchography and in the examination of the spinal canal (myelography).

5. Fluoroscopy.—Fluoroscopy has a great advantage over filming in that with it motion can be seen, but there are many offsetting disadvantages, the most important of which is the inevitable radiation hazard to operator and patient. In addition, fluoroscopy lacks objectivity because it leaves no permanent record, and in the case of the simple fluoroscope the image on the screen is so faint that to see it the room must be well darkened and the eyes of the fluoroscopist fully dark-adapted. For more than 50 years the simple fluoroscope (see above) had no competitor, but after two decades of experimentation and development a sophisticated adaptation of television seems destined to supplant it. A Coltmantype image amplifier converts a visible fluoroscopic image into an electron image and then electronically accelerates and focuses the electrons, delivering them to a secondary screen where they produce a small but very bright visible image. A television camera tube receives the small image from the amplifier and after further electronic amplification displays it on one or more viewing tubes. In the best modern sets images of acceptable quality can be obtained even in the case of heavy patients at low-tissue doses. That the work can be carried on in a reasonably well-lighted room has many advantages including the fact that the examiner's eyes need not be dark-accommodated.

Photofluorography.—From the earliest days of radiology, attempts were made to make permanent records of fluoroscopic images by photographing them, but until the late 1930s the maneuver saw little practical application. The advantage of photofluorography lay in its ability to employ small, inexpensive and easily processed photographic roll film instead of large, costly,

individual sheets of X-ray film, its disadvantage in the fact that fluoroscopic images were faint and the camera lenses available for recording them slow. As far as the chest is concerned, the disadvantages finally were overcome by developing faster film emulsions, faster screens and refractor lenses large enough to cover a 64-mm. by 70-mm. area on roll film and yet having a speed of $f/1.5$. Millions of members of military and civilian populations were subjected to small-film chest surveys, but though such photofluorography of the chest is of genuine importance as a public health measure it is not a rival of the older methods as a means for the detailed study of pulmonary diseases.

The substitution of large-aperture reflector lens systems for the $f/1.5$ refractors improved the quality of chest microfilms and reduced the X-ray dose to the patient. Recently lens manufacturers have produced for photofluorography refractors of good resolving power with speeds approaching or even equaling those of reflectors.

X-Ray Motion Pictures.—Within a year following Wilhelm Conrad Röntgen's announcement of the discovery of X-rays, attempts were made to produce X-ray motion pictures. Scores of publications on the subject appeared thereafter in the public and scientific press. In the so-called direct method a motion-picture positive is made from a sequence of individual X-ray negatives; in the indirect method the positive is printed from a motion-picture negative of the fluoroscopic screen. Both methods required such large doses to the tissues of the subject that they were limited to experimental work with animals; in the case of the indirect method, however, modern image amplifiers have removed this difficulty, and 16 mm. (to a lesser extent also 35 mm.) X-ray motion-picture films are becoming valuable practical clinical tools. For the best photographic detail the camera photographs the output phosphor of the Coltman-image tube; but for many purposes it is possible to reduce the tissue dose and still obtain acceptable images by photographing instead the televised image. An example of such clinical applications is the "voiding urogram." A patient suspected of having mechanical or neurogenic interference with the mechanism of emptying the bladder has the urine in his bladder opacified by one of the pyelographic contrast media, which may be injected intravenously, introduced through a urethral catheter, or occasionally introduced through a needle passing through the skin and other tissues overlying the bladder. So prepared, the patient stands before a vertical fluoroscope and voids during the making of a motion-picture film. The study of such films with varying projection speeds frequently provides an explanation of previously obscure urinary tract mechanics and may lead to corrective surgery.

X-Ray Video Tape.—At least as important as motion-picture film is the use of video tape in connection with television type fluoroscopy. The apparatus is expensive; so is the tape, but it can be reused repeatedly once it has been reviewed and its more significant portions recorded on photographic film. In the past the fluoroscopist had to depend on brief notes, sketches and memory as he dictated the reports on his examinations. Now, thanks to tape, he can restudy the entire examination if necessary, and if the need arises he can enhance his report to the referring physician by a visual demonstration.

C. APPLICATIONS

1. Teeth.—Intraoral films were early employed for detecting abscesses in the bone about the apexes of the teeth, for locating unerupted or impacted teeth and for discovering retained broken tooth roots. Their field of usefulness was enlarged until they came to play an important part even in the periodic examination and cleaning of the teeth. Small cavities at abutting surfaces, poorly fitting fillings and inlays, recession of the bone from the necks of the teeth and, most important of all, subgingival deposits of salivary calculus—such lesions as these are easily detectable in X-ray films though they may escape all but the most skillful and searching direct inspection.

2. Bones.—For the first few years following Röntgen's discovery, it seemed that X-rays might be used in medicine chiefly as an aid in the diagnosis and reduction of fractures. X-ray films are

used not only for the detection of injuries but also for demonstrating the presence of tumours, infections and almost every other form of skeletal disease. In normal bone the cortex shows in X-ray films as a dense amorphous shell and the spongy portion as a honeycombed structure made up of the shadows of the coarse primary trabeculae, on which are superimposed the shadows of the fine secondary trabeculae. Disuse of living bone causes a generalized loss of density known as osteoporosis, but when portions of bone are killed by disease or injury before osteoporosis has occurred, they retain their original density for long periods of time. Some tumours and infections cause localized destruction of bone and others cause the bone to become denser than normal (sclerosis). Certain parts of normal living bone, such as marrow, periosteum and articular cartilage, though not themselves discernible by X-rays, may when diseased produce subtle changes in visible bone adjacent to them, thus leading to their own detection. Rickets, scurvy, syphilis, tuberculosis, Paget's disease (osteitis deformans), benign and malignant tumours and many other skeletal diseases produce changes in the X-ray appearance of bones that are almost always easy to see and frequently so characteristic as to warrant a specific diagnosis.

3. Chest and Heart.—Internists and surgeons must lean heavily on the findings of the radiologist for the detection and management of such pulmonary diseases as tuberculosis, pneumonia and cancer, though of course it is necessary to weigh all the evidence in making the final diagnosis and not depend on X-rays alone. Active fibrocaseous tuberculosis usually produces rather characteristic dense splotches in one or both of the lung apices, but at certain stages in their course some of the pneumonias and histoplasmosis show X-ray patterns almost identical with those of tuberculosis. Malignant tumours arising in the bronchi usually reveal themselves promptly by causing bronchial obstruction with resulting rather typical areas of lung collapse. Foreign bodies accidentally introduced into the trachea or bronchi frequently are dense enough to show directly in X-ray films; when radiotranslucent they may be detectable with the aid of opaque media or by virtue of changes they produce in the air patterns of the lung. When the diagnosis of pulmonary tuberculosis has been established, repetition of the X-ray examination is one important method for observing the results of treatment.

Radiology may be employed to determine the size and shape of the heart and great vessels, and, with the aid of opaque media, it provides detailed information about the chambers and valves of the heart and the pulmonary vessels, particularly in children suffering from congenital defects.

4. Skull, Brain and Spinal Cord.—The X-ray criteria employed for diagnosing injuries and diseases of bone are most dependable in regions where cortex is thick and well differentiated from spongiosa, as in the long bones of the extremities. Cortex is well developed in the vault of the skull, and fractures, tumours, infection, etc., in the skull are usually reasonably evident. In the face bones, however, where the cortex may be as thin as paper, such lesions may be almost invisible.

Because of the air that they contain, the normal mastoids and the sinuses (frontal, ethmoid, maxillary, sphenoid) show as black shadows sharply silhouetted against bone, and if fluid or benign or malignant tumours are present they too will stand out in contrast with the air. Certain tumours of the pituitary gland cause the sella turcica to enlarge in a characteristic fashion, and in young children a long-continued increase in intracranial pressure may be inferred from a resulting separation of the bones of the skull.

The brain itself is radiotranslucent except for several normal and occasional pathological patches of calcification, and so it is necessary to employ contrast media when the brain is to be examined, the medium of choice being oxygen or air. When such gases are introduced into the subarachnoid space, the procedure is termed *encephalography*; when they are injected directly into the hollow chambers or ventricles at the centre of the brain it is called *ventriculography*. In either case, the X-ray examination is done with stereoscopic films, and the object is to study the internal and external contours of the brain by virtue of the gas

that is in contact with them. Development of cerebral angiography (see *Blood Vessels*, below) greatly expanded the radiologist's ability to diagnose tumours of the brain and small aneurysms of the cerebral vessels.

Opaque media are much more effective than gas for examining the spinal cord and the canal in which it lies, a procedure known as myelography. Under fluoroscopic control, the contrast material in the subarachnoid space is maneuvered into all parts of the spinal canal from the tip of the caudal sac in the lumbosacral region up to (but not into) the cisterna at the base of the brain. The films that are made at all levels and in several positions show the cord itself as a translucent or negative shadow and the surrounding subdural space as a dense shadow by virtue of the opaque medium it contains. Protruding knobs of intervertebral cartilage, spikes or ridges of arthritic osteophytes, tumours of bone, cord or meninges are among the abnormalities that may be detected by myelography; but normal variation is great and differentiation difficult even when the examination is conducted by teams of specially trained neurosurgeons and radiologists.

5. Gall Bladder and Bile Ducts.—In 1923 E. A. Graham introduced a method for the X-ray examination of the gall bladder, known as cholecystography, which came into universal use. An iodized organic compound contrast medium, after being given by mouth in tablet form, is absorbed from the gastrointestinal tract into the blood and then removed from the blood stream by the liver and combined with the bile. A normal gall bladder, receiving through its cystic duct watery, weakly iodized bile, concentrates it until eventually it becomes thick and its iodine content high. In X-ray films made 10 to 15 hours following administration of the opaque medium, the normal gall bladder casts a dense shadow and any cholesterol stones present stand out as negative shadows against the iodized bile. If the gall bladder is seriously diseased or its cystic duct is occluded, bile will fail to reach the gall bladder or, reaching there, will fail of concentration, either of these events resulting in nonvisualization.

Cholangiography, or examination of the bile ducts, usually is conducted in conjunction with surgery to assure that stones or a tumour obstructing the ducts have not been overlooked. A contrast medium is injected either through a T tube tied into one of the bile ducts or by means of a hypodermic needle introduced through the wall of a duct or of the gall bladder itself. Intravenous cholangiography (*i.e.*, with contrast medium injected into a vein), introduced in the late 1950s, met with limited success.

6. Urinary Tract.—Pyelograms are X-ray films of the urinary tract made following the introduction of an opaque medium. In the retrograde method, the opaque medium is injected through ureteral catheters introduced with the aid of a cystoscope. In the excretion or intravenous method, it is injected intravenously followed by filming at intervals of 5 to 15 minutes.

Most tumours lying in the fleshy part of the kidney outside its collecting system compress, stretch and otherwise distort the calyces and pelves. Tuberculous abscesses are prone to break through into the calyces, allowing the opaque medium to extravasate into diseased tissue, and the infrequent kidney stones that are radiotranslucent may be rendered visible by the opaque medium in the same way that opaque medium reveals cholesterol gallstones. Cystograms are films of the urinary bladder made after the direct or excretory filling of that organ with opaque medium. Bladder tumours, diverticula and urethral obstruction by chronic prostatic enlargement produce rather characteristic alterations in the appearance of the cystogram. By means of motion picture "voiding cystograms" (see discussion of voiding urograms, above) it can be shown that in some cases there is gross reflux of urine into ureters and kidney pelves during the act of voiding.

7. Female Reproductive Tract.—Sterility of the human female may result from various causes, one of which is occlusion of the fallopian tubes. The best means of demonstrating such occlusion is to make X-ray films following the injection of iodized oil into the uterus. In the normal subject, the oil passes out through both fallopian tubes to spill into the peritoneal cavities, where, 24 hours later, it becomes smeared over the serous surfaces of loops of bowel and appears by X-ray as a slightly opaque, crum-

BY COURTESY OF DEPARTMENT OF RADIOLOGY, UNIVERSITY OF CHICAGO

DIAGNOSTIC USES OF X-RAY

(Top) Blood clot compressing left hemisphere of the brain. X-ray film was made following injection of contrast medium into an artery in the neck (left carotid angiogram). (Bottom) Partial obstruction of abdominal veins caused by Hodgkin's disease. X-ray detected enlarged abdominal lymph glands compressing the vena cava and forcing blood through the network of small veins at the left side of the spine (left ascending lumbar veins). 30 cc. of 60% contrast medium were injected into the external iliac veins of both thighs before the film was made. In both X-rays, patient's right is at reader's left.

pled veil. When no connection exists between the uterine cavity and the peritoneal cavity, the peritoneal spread of the oil does not occur, and when occlusion is due to saclike adhesions about the outer ends of the fallopian tubes, the oil breaks up into droplets and is retained in the watery fluid that fills the sacs. While the purpose of the injection is diagnostic, it is believed that it may sometimes be therapeutic as well, breaking up adhesions if they are not too tough and developing communication where none existed before.

When a pregnant woman is known to have an obstetrically adequate pelvis and a presumably normal fetus, pelvic X-ray examination seldom is called for, but if circumstances require quantitative knowledge as to the dimensions of the birth passages, X-ray examination provides by far the best means of measuring them.

Since X-rays diverge from their point of origin, the X-ray images of anatomical parts that are parallel with the plane of the film are always somewhat larger than the parts themselves; and if the parts are oblique to the film, that too causes distortion of the image. With the aid of a little special equipment and the application of a little simple geometry it is possible to compensate for distortion and translate measurements of film images into the actual dimensions of the maternal or fetal parts they portray, the procedure being known as pelvimetry or fetometry.

8. Blood Vessels.—For many decades injections of opaque heavy metal salts were used for making X-ray films of the blood vessels of anatomical specimens, and later angiography of the living subject became of clinical importance. When vessels of the brain are to be injected, most radiologists prefer to use the contrast material in 30% concentration, but for the chambers of the heart and the great vessels leading from them concentrations as high as 70% are necessary. Several films must be made in rapid succession, each exposure being brief, the first in the series phased carefully with the beginning of the injection. Some radiologists use long strips of roll film driven past a window that is transparent to X-rays but opaque to light, while others prefer cut film carried in motor-driven conveyers.

In the 1960s radiologists and vascular surgeons throughout the world regularly investigated and frequently solved vascular-tract problems, some of which were unsuspected, much less capable of solution, a decade earlier. These include congenital absence or variation of blood vessels and congenital or acquired blockage or dilatation of blood vessels in all parts of the body, including those of the brain and of the lungs. Workers of many nationalities laid the groundwork for modern vascular radiology, those in Sweden playing a particularly important role.

9. Stomach and Intestine.—X-ray examination is an important, almost indispensable, agent in the diagnosis of gastric and duodenal ulcer; benign and malignant tumours of the esophagus, stomach and bowel; diverticulosis and diverticulitis; ulcerative colitis; regional ileitis; and several other diseases. Barium sulfate is the contrast medium almost invariably employed. Formerly it was fluoroscopic examination that made the diagnosis, with films occupying a position of secondary importance, but many modern radiologists look upon fluoroscopy largely as a means of obtaining small, so-called spot films of various parts of the tract. In spot filming, the fluoroscopist manipulates a small segment of the gastrointestinal tract into position beneath the fluoroscopic screen and adjusts the amount of barium that it contains and the pressure applied to it until he has an optimum view. A film is now brought into position between the patient and the fluoroscopic screen, and, when the X-ray machine setting has been changed from the continuous small current adequate for fluoroscopy to the high voltage and large currents needed for rapid filming, the exposure is initiated with a foot switch and terminated automatically with a phototube. Television fluoroscopy is especially useful in examination of the alimentary tract and some progress has been made toward the substitution of video tape and photographs of the output phosphor of the Coltman tube for direct spot films.

Ulcers usually deform the outline of the stomach or duodenal bulb and, in addition, frequently excavate craters which, when filled with barium, are highly diagnostic. Cancers appear as soft tissue masses protruding into the lumen of the stomach or bowel and distorting the appearance of the gastric or intestinal mucosa.

II. THERAPEUTIC RADIOLOGY

One of the most remarkable attributes of the X-rays that Röntgen discovered in 1895 was the seemingly innocuous way in which they penetrated human tissue without causing pain, a feeling of heat or any other immediate sensation; but it did not take long for experimenters to learn that in spite of the absence of imme-

diate effect, large doses led presently to redness of the skin, blistering and ulceration. Even small doses, it was found, if repeated often enough were followed by serious skin lesions that showed up only after a considerable lapse of time. Of course, an agent so capable of damaging normal tissue was bound to be considered for employment therapeutically if some means could be found to direct its damaging effects specifically against diseased parts.

Something eventually was learned about the fundamental nature of the biological action of radiation, and research on this subject continues, but usefulness did not wait on a complete understanding. Radiation therapy became one of medicine's few means of restraining and in some cases curing cancer.

The radiations employed in therapeutic radiology include X-rays ranging in voltage from about 5 kv. to more than 4,000 kv., radium, artificial radioisotopes, electrons, neutrons and other high-speed particles. Important differences in the physical distribution of the dose determine which of these should be used for a particular application, but biologically speaking it is the similarities rather than the differences that are most obvious throughout the entire range from the low-voltage X-rays used in contact therapy to the high-speed particles of the largest cyclotrons.

For historical and other reasons a discussion of radium and low- and medium-voltage X-ray therapy lends itself particularly well to an exposition of principles that apply throughout the entire radiation range. It is for this reason alone that radium, artificial radioisotopes and X-rays of low (5–100 kv.) and medium (100–400 kv.) voltage are emphasized below. This distribution of emphasis should not be misinterpreted as indicating that multi-million-volt X-rays and high-speed particles are clinically unimportant.

The ideas of Heinrich Geissler, J. W. Hittorf, Sir William Crookes and P. E. A. Lenard were important immediate antecedents to those of Röntgen, and in the years after 1895 the stream of those ideas was swelled by innumerable tributaries. Italians such as Enrico Fermi supplied ideas in nuclear physics. Frenchmen such as the Curies, H. Coutard, A. Lacassagne and C. Regaud discovered radium and established the importance of the time factor as a modifier of the reaction of tissue to radiation. German physicists made important contributions, and German physicians such as H. Holthusen studied large masses of clinical material to establish much empirical knowledge. Scandinavians typified by G. Forssell and R. Sievert refined and advanced dosimetry and made large-scale clinical application of facts established in the laboratory.

British contributions were of two sorts. In the closing decades of the 19th century and the opening decades of the 20th such physicists as J. J. Thomson, C. T. R. Wilson, H. G. J. Moseley and the two Braggs led in the development of X-ray physics, and later such physicians as Ralston Paterson and David Smithers and such radiation physicists as W. V. Mayneord, W. J. Meredith and H. M. Parker increased the precision with which radiation beams might be regulated and directed and advanced knowledge as to the response of normal and diseased tissues to such beams.

In the U.S., W. D. Coolidge conceived and produced X-ray tubes superior to anything available before, and Arthur Holly Compton and his students, employing X-rays to study the nature of matter discovered in the process new and important facts about the X-rays themselves. Ernest Lawrence's pioneering cyclotron typified a whole group of instruments developed for accelerating particles of various sorts, and the biological experiments on ionizing radiation that were carried on during World War II under John Lawrence in California and under Robert Stone in Chicago served as patterns for many later similar activities.

A. DOSAGE

1. Measurement.—The dose employed in X-ray therapy cannot be defined merely by stating the voltage and current at which the X-ray tube is operated. Numerous other factors are involved, including diameter and filtration of the X-ray beam, target-skin distance and the size and location of the lesion being irradiated. The need of dependable dosage guides was recognized more or less clearly from the outset, but their development proved diffi-

cult. Tried and found wanting were the measurement of the heat produced by the absorption of X-rays; the intensity of fluorescence; colour changes in several different combinations of chemicals; the blackening of silver bromide paper; the liberation of iodine from a solution of iodoform in chloroform; and an increase in the electrical conductivity of selenium under the action of X-rays.

Ionization Methods.—Röntgen's original papers described the ability of X-rays to ionize air, and in 1896 J. J. Thomson independently discovered the effect and suggested its use by physicists as a means of measuring X-ray intensity. P. Villard in 1908 advocated ionization for measuring the clinical dose, but his idea was not practical at that time because the large, delicate ionization chambers that were serving physicists so well were not suitable for clinical work and no others were available. Gradually, however, small rugged chambers were developed, and in 1928 at the second International Congress of Radiology in Stockholm, Swed., there was adopted the "r" or roentgen unit, which became the standard throughout the world.

Roentgen Unit.—The roentgen unit was defined in Stockholm as follows:

The unit of dose is that quantity of roentgen radiation which, when the secondary electrons are fully utilized and the wall effect of the chamber is avoided, produces in 1 c.c. of atmospheric air at 0° C. and 760 mm. mercury pressure such a degree of conductivity that one electrostatic unit of charge is measured under saturation conditions.

This definition sufficed as long as the X-rays to be measured were produced at voltages up to 200 kv., but as r meters began to be employed in the 1,000-kv. range and for the gamma rays of radium, the following definition was substituted:

The roentgen shall be the quantity of X or gamma radiation such that the associated corpuscular emission per 0.001293 g. of air produces, in air, ions carrying 1 esu of quantity of electricity of either sign. (The mass of 1 c.c. of dry atmospheric air at 0° C. and 760 mm. of mercury pressure is 0.001293 g.)

Rad.—When the absorbed dose is the chief matter of interest, the roentgen unit has the disadvantage that absorption in air is independent over a considerable wave-length range, whereas in water-containing tissues energy absorption per gram increases from approximately 84 ergs for long-wave-length (low-voltage) radiation to about 93 ergs per gram for short-wave-length (high-voltage) radiation. The unit of absorbed dose is the rad, representing the amount of radiation which delivers energy equivalent to 100 ergs to a gram of irradiated tissue.

Roentgen (r) Meters.—The condenser-type r meters in general use in the United States consist of two parts, a chamber-condenser unit and a charging-measuring unit. Three sizes of chamber usually are supplied: a large one that measures up to 25 r; an intermediate size measuring up to 100 r; and a small chamber for measurements up to 250 r. The electrometer that measures the charge has three corresponding scales calibrated from 0 on the left to 25 r, 100 r or 250 r, respectively, on the right.

Chamber-Condenser Unit.—In the 100-r unit the chamber itself is a small plastic thimble that contains one cubic centimetre of air at room temperature and pressure. The inside of the wall of the chamber, which has been rendered conducting by a thin coating of carbon, constitutes one electrode and is connected to the metal sheathing that forms one of the plates of a 60-micro-microfarad condenser. The second electrode is a carbon-coated plastic rod mounted in a block of high-impedance material with its tip protruding into the air in the chamber, its base in electrical contact with the insulated plate of the condenser. Care is taken to exclude air from all parts of the system except the space inside the chamber itself.

Charging and Measuring Unit.—The charging and measuring unit consists of a hand-driven plastic disk that generates a static charge by rubbing against a leather pad, plus a quartz fibre electroscope that is calibrated in roentgen units. In using the instrument, the condenser is plugged into the charging unit and the charging wheel is rotated until the fibre stands at 0. The charged condenser is then disconnected from the electrometer and placed for a measured period of time with its chamber in the beam of the

X-ray that is to be measured. The X-rays ionize the air in the chamber, causing it to become an electrical conductor, and this in turn allows the charge on the central plate of the condenser to leak to the wall of the chamber and thence to the outer plate of the condenser. When the partially discharged condenser is reconnected to the electrometer, the fibre has moved from the fully charged 0 position on the left toward the discharged 100-r position on the right, the precise amount of loss of charge being read directly in roentgens without computations of any sort.

Roentgen meters of this sort are secondary standards requiring initial checking against large standard chambers and occasional subsequent rechecking, but when they are carefully built and properly calibrated their accuracy is well within the limits necessary for radiation therapy. The required dose varies widely from as little as 1,200 r in some lymphomas to as much as 5,000 r in most laryngeal carcinomas.

2. Low-Voltage X-Rays.—Until the close of World War I most clinical X-ray apparatus could not be operated at voltages in excess of 100 kv.; while this was more than enough for diagnosis, it limited therapeutic applications to lesions lying at or close to the surface of the body. Regardless of the inciting voltage, the raw beam as it leaves the X-ray tube contains amounts of long-wave-length radiation that are enormously greater than the amounts of short-wave-length rays. Because the long-wave rays are easily absorbed, they are said to be soft, while the short penetrating rays are said to be hard.

If raw radiation from a tube operated at 100 kv. is allowed to fall on a patient's skin, the soft radiation will be strongly absorbed in the superficial layers, so that an exposure time long enough to result in serious skin damage delivers only small amounts of relatively hard radiation to tissues lying a few centimetres beneath the surface. Filtration through three millimetres of aluminum will harden such a beam so that it may be possible to deliver 20% of the surface dose to tissues five centimetres beneath the surface, but it is impractical to deliver doses of therapeutic magnitude to tissues ten centimetres below the surface unless the voltage at the X-ray tube is raised well above 100 kv.

Formerly the degree of reddening of the skin was used as an indication of the dose, but this so-called erythema dose had serious limitations and was abandoned in favour of actual tissue doses expressed in roentgens. Along with the conception of erythema dose went also an indiscriminating attitude toward the employment of radiation for almost any of the cutaneous diseases. Radiation has its place in dermatology, but it is dangerous as well as useful and its employment must be restricted to physicians who are specially trained in its use. Under competent supervision, low-voltage X-rays are indicated in the treatment of such conditions as small- to moderate-size skin carcinomas, large keratoses, obstinate circumscribed neurodermatitis, plantar warts, superficial hemangiomas, ringworm of the scalp, cutaneous lymphomas and Kaposi's sarcomas, but in skin lesions if drugs and other agents will suffice these should be used in preference to X-rays.

Contact Therapy.—Much of the very soft radiation produced at any operating voltage is absorbed in the glass wall of the X-ray tube, and when voltages are reduced below 30 kv. almost none of the rays are hard enough to pass through the glass. For some of the vascular birthmarks, keloids, skin cancers and certain other skin lesions, it is desirable to be able to irradiate superficial tissues heavily with only a minimum dose to deeper structures. This is made possible by special X-ray tubes in which the port for the emergence of the radiation is a thin sheet of beryllium rather than glass. Such tubes are operated at voltages of the order of five peak kilovolts and the circuits are arranged so that it is safe to press the port against the skin of the patient. These three factors—closeness of the target to the skin, low operating voltage and minimum beam filtration—operate to minimize the depth dose and maximize the dose at the surface.

3. Medium-Voltage X-Rays.—By 1915, German scientists had added three concepts and a group of associated techniques which became basic to the radiation therapy of deep-lying lesions. These concepts were: the role of voltage, filtration and the geometry of patient and X-ray beam in determining the dose delivered to

deep-lying tissues. The techniques were Walter Friedrich's thimble chamber for measuring the dose in air, body cavities, wax, water, etc., and Friedrich Dessauer's 200-kv. X-ray generators, isodose charts, and employment of wax, water bags and similar material to reduce the patient's body to a straight-sided geometric form to which his isodose charts could be applied. In the next three decades knowledge and experience advanced enormously; but Dessauer's paper, presented in 1921 to the American Roentgen Ray society, lacked little that is really fundamental to an understanding of medium-voltage X-ray therapy as it is now practised.

Increasing the voltage to 200 kv. made it possible to treat deep-seated lesions, most of which had been inaccessible before; but raising it another 50 kv., though desirable, did not prove to be essential. Increasing the voltage still further to 400 kv. brings additional advantages, but most workers agree that they are more than offset by decreased flexibility and considerably greater cost.

There are certain practical advantages in raising the voltage of X-ray therapy machines to 1,000 or even 2,000 kv., but, as in the case of cobalt-60 (see *Artificial Radioisotopes*, below), there is no specific advantage in the shorter-wave-length radiation thus produced.

4. Radium.—Opinion as to the clinical importance of radium (*q.v.*) fluctuated widely after the discovery of this element was announced by the Curies in 1898. Administered internally, it is a slow but lethal poison devoid of any therapeutic value; but confined in airtight needles or capsules, sheathed with a filtering layer of $\frac{1}{2}$ mm. or more of platinum, it constitutes a gamma-ray emitter of established clinical importance. Radium needles or capsules having only thin layers of brass or Monel metal as filters emit large quantities of electrons or beta rays and are of only limited clinical value.

The hardest gamma rays of radium have a hardness or penetrating power approximately equivalent to the hardest of the X-rays produced at 3,000 kv.; but paradoxically the important medical role of radium is to deliver large ionizing doses to superficial tissues while minimizing the effect at a depth. The explanation lies in the geometry of the situation. Gamma rays, like X-rays, diverge from their point source of origin in a solid angle of 4π , so their intensity falls off as the square of the distance from that point of origin. Radium usually is employed in rods of appreciable diameter and length which act as multitudes of point sources re-enforcing one another, but to simplify the explanation that follows, it will be assumed that the radium has been concentrated in a single minute sphere. Since it is possible to bring the source of the gamma rays into almost full contact with surface tissue, it follows that tissues one centimetre distant from that source will receive only about 1% of the dose that is delivered at the surface, and tissues five centimetres distant only about 4% of the dose delivered at one centimetre. (These values ignore losses by absorption and gains by scattering, though both must be taken into consideration in actual practice.)

In a few instances several grams of radium have been concentrated in heavily shielded containers that can be backed off five to ten centimetres from the surface of the patient's body. Such gamma-ray beams filtered through one millimetre of platinum deliver depth doses distinctly better than those obtained with radium at the surface or inserted into the body but are inferior in this respect to well-filtered 250-kv. X-rays from tubes stationed 80 cm., 60 cm. or even 50 cm. away from the surface of the body. These so-called telecurie radium applicators would lose all justification with the availability of megacurie radiocobalt applicators, but heavily filtered interstitial and intracavitary radium employed sometimes alone and sometimes in conjunction with X-rays meanwhile continued to be important.

5. Artificial Radioisotopes.—In addition to the series of naturally occurring radioisotopes of uranium known collectively as radium which emit gamma radiation and have an aggregate half life of 1,590 years, there are available as products of cyclotrons and nuclear reacting piles a great number of artificial radioisotopes of many different elements. In some of these the radiation intensity decays to half its initial value in fractions of micro-seconds, while others have half lives longer than that of radium.

A few of these isotopes had been investigated clinically by the early 1960s, but most of such work remained to be done. Phosphorus-32 administered intravenously as a sodium phosphate in doses of one to two millicuries a week for four to eight weeks is employed for the treatment of chronic leukemia. Iodine-131 administered orally as a solution of sodium iodide in doses of six to eight millicuries, repeated if necessary at trimonthly intervals, is used to reduce excessive activity of the thyroid gland, and occasionally cancer of the thyroid responds favourably to much larger doses. By the second half of the 20th century there was great interest in the clinical possibilities of cobalt-60. Megacurie cobalt applicators possess many of the virtues that are lacking in, and avoid most of the faults that are inescapable in, telecurie radium applicators. The charge of radioactive Co^{60} , though weighing only 12 g. and comprising a rod only 0.7 cm. in diameter and 3 cm. in length, will produce gamma rays of 1.13 and 1.32 Mev with a source intensity more than 200 times that of the same weight of pure radium or 260 times that of radium chloride. The decay of intensity by one-half within 5.3 years requires occasional substitution of new cobalt and the consideration of decay time in computing the output of the applicator, but at most these are only minor inconveniences. To shield against unwanted gamma radiation, the container is constructed of uranium 13 cm. thick or lead 26 cm. thick; the removal of all beta radiation from the beam requires merely a thin aluminum filter. With such a cobalt source stationed 80 cm. distant from the skin, the surface dose to a 5 cm. by 5 cm. area is approximately 35 r per minute and the dose 10 cm. beneath the surface is 18.2 r per minute.

As radiologists acquired experience and manufacturers improved design it became obvious that telecobalt applicators could take over all the work formerly done by 250-kv. X-ray machines in addition to having certain potentials beyond the scope of such machines. It seemed probable that American manufacturers would discontinue the production of 250-kv. X-ray generators, which had long been looked upon as the "workhorses" of the radiation therapist. Cesium-137 applicators have the advantage over cobalt-60 in that their half-life is several times longer and their radiation less penetrating, with resulting saving in the thickness and weight of primary and secondary protective barriers. On the debit side is the fact that curie for curie a cesium-137 source has physical dimensions considerably larger than those of a cobalt-60 source, so that avoidance of penumbra requires a long source-tissue distance and scrupulous designing of collimating devices.

B. RADIATION PHYSICS

The work of calibrating X-ray machines, mapping the doses of the radiation that is purposely delivered to the tissues of a patient's body and protecting patients and radiation workers from unwanted radiation is a subspecialty within the specialty of radiation therapy. Modern treatment centres require the full-time services of considerable numbers of graduate physicists specially trained in this branch of physics. Much oversimplified, dose mapping may be summarized as follows:

The intensity and hardness of the X-ray beam are adjusted by varying the operating voltage and current and the nature and amount of interposed filter. For example, one combination will be found which yields a beam that will have its intensity reduced to one-half by the addition of a testing filter of one millimetre of copper. Such a beam is designated as having a hardness of one millimetre of copper half value layer (mm. Cu. hvl.). Another combination will yield a hardness of 1.5 mm. Cu. hvl., and a third a hardness of, for example, 3 mm. Cu. hvl.

These calibrations depend on r meter measurements of the beam with and without the added test filters, and from time to time the physicist checks them with his meter, but for the day-to-day work beam hardness is adjusted merely by selecting the interposed filter, voltage and current indicated on the calibration charts.

Other tables are prepared showing the dose in roentgens per minute measured at points located, for example, 50 cm. and 80 cm. from the target of the tube.

From roentgen measurements made with the thimble cham-

ber at the surface and inserted into phantoms of wax, water or similar absorbing and scattering material, tables and isodose charts are prepared to show the doses that will be delivered at various points beneath the surface for given beam hardness, tube-skin distance, beam diameter and minute surface intensity.

It is the responsibility of the clinical radiologist to judge as closely as possible the size and location of the lesion, the amount and delivery rate of radiation most likely to be effective, and the tolerance of neighbouring uninvolved tissues. When this has been done the physicist determines the hardness intensity, geometry and aiming of the single or multiple beams best suited to place the radiation in the amounts and at the points stipulated, following which the technician administers the treatment as directed.

Employing merely his slide rule, graphs and tables, the skilled radiation physicist frequently required hours of painstaking work to plan the geometry and determine the "air doses" necessary to deliver "tissue doses" of desired magnitude to tissues of stipulated dimensions located at stipulated distances beneath the surface. Properly programmed computers, however, can perform such tasks in minutes; therefore they are being employed increasingly.

The usefulness of the physician-radiologist is enlarged greatly by such assistance from physicists and technicians, but it is necessary that he be competent in their fields as well as his own; legally as well as morally he must be responsible for the whole.

C. CLINICAL ASPECTS

The tissues of the body are unaffected by radiation that merely passes through them; it is only absorbed radiation that produces an effect. When there is an effect it is invariably cell injury, and the direct agency in this injury appears to be the ionization invariably associated with absorption.

The relationship between the degree of ionization and the nature and magnitude of the biological response is constant throughout the low- and medium-voltage range. In the multimillion-volt range, direct comparison is difficult because measuring instruments regularly employed for lower-voltage radiation are no longer fully dependable and the type of ionization itself changes slightly. It seems probable, however, that with the change in type of ionization there is an advantageous alteration in the ratio between the intensity of ionization and the magnitude of cell response.

Opinions differ as to whether radiation should be used to treat nonmalignant conditions such as arthritis, bursitis and hypertrophic lymphoid tissue. The former view—that such therapy, though possibly ineffective, certainly was innocuous—no longer is tenable, and physicians increasingly believe that X-ray treatment should not be employed where other therapeutic methods are available. On the other hand, the value of radiation in the treatment of cancer is established beyond all argument (see CANCER; CANCER RESEARCH). In the radiation therapy of cancer both the effect on the host and the effect on the diseased tissue are important. The body is not totally without natural defenses against cancer, but those defenses usually are not quite adequate and new cancer cells develop more rapidly than old ones are destroyed.

The aim of the radiation therapist is to deliver major damage to cancer cells with minimum damage to the adjacent normal tissue, hoping to tip the scales to such an extent that the natural defenses of the body will regain the upper hand. When too large a dose is given, cancer growth may be increased rather than diminished because the restraining action of a healthy tissue bed has been lost. There has been much investigation of physical and chemical conditions which seem to enhance the effect of ionizing radiation on neoplasm. A promising possibility is that hyperbaric oxygen may play such a role.

Radiosensitivity of tumours is influenced by numerous factors including cell type; tumour size and location; and age and general health of the host. Small tumours located rather superficially in young and otherwise healthy patients respond better

than do large deep-seated tumours in debilitated elderly patients. Grouped in order of decreasing sensitivity, the response by cell type is as follows: (1) lymphocytes; (2) granulocytes; (3) epithelial cells, (a) basal cells of secretory glands, (b) basal cells of testes and ovaries, (c) basal cells of skin and intestinal tract, (d) alveolar cells of lungs, bile ducts, and (e) tubules of kidneys; (4) endothelial cells; (5) connective tissue cells; (6) muscle cells; (7) bone cells; (8) nerve cells.

The probability of clinical cure is not proportional to the degree of cell sensitivity, however. For example, the cells of Hodgkin's disease are extremely sensitive to ionizing radiations, but, though patients skillfully treated respond strikingly at first, this favourable response seldom is permanent. On the other hand, cancer of the cervix of the uterus with cells much less sensitive than Hodgkin's tissue can be cured. Skin cancer is curable unless it has been neglected until it has extensively invaded bone or cartilage. Cancer of the larynx, nasopharynx and tongue are particularly suited to radiation therapy because the mutilation incident to surgical extirpation is so disabling. Cancer of the cervix of the uterus responds well to radiation and cancer of the body of the uterus to surgery combined with radiation. Cancers of the stomach and bowel are best treated surgically. In many cases where there can be no expectation of cure, radiation may provide relief from pain and frequently considerable prolongation of the period of usefulness and relative comfort.

RADIOMETER, an instrument for measuring the intensity of radiant energy. The term is applied most often to instruments of the vane type described below, but it can also be applied to the bolometer, pyrheliometer, thermopile and radio balance. For information on these instruments see HEAT: Radiation.

It was noticed by A. J. Fresnel that a body delicately suspended *in vacuo* is apparently repelled by radiation. Using this principle, Sir William Crookes constructed an instrument, which he called a radiometer, by pivoting a vertical axle carrying vertical vanes inside an exhausted bulb; one side of each vane was blackened and the other side bright, the black sides all facing the same way round the axle. When rays from the sun or other light source or dark radiation from a warm body fall on the vane, the black sides are repelled more than the bright sides, and the vanes are set into rotation. The more intense the radiation the more rapidly do the vanes rotate. It was Crookes's idea that the instrument might be used to measure the intensity of radiation.

Instead of allowing free rotation of the vane system on a pivot, it may be suspended by a quartz fibre. Radiation falling on the black face of the vane will then cause the system to turn round until the restoring couple, because of the torsion of the suspension, balances the deflecting couple due to the radiometer action. A small mirror, attached to the vane system and reflecting a beam of light on to a scale, permits very small deflections to be observed. Ernst Pringsheim constructed such an instrument in 1883 and used it for spectrographic investigations in the infrared. In 1893 E. F. Nichols improved the radiometer by using mica vanes,

one at each end of a horizontal arm suspended on a quartz fibre and each blackened on its front surface. Radiation falling on both vanes would tend to turn them in opposite directions, and if they were correctly adjusted the system would not move under the influence of general stray radiation. The radiation to be measured was allowed to fall on one only of the vanes, and the resulting deflection of a spot of light was observed. With such a radiometer Nichols was able to measure the radiation from individual stars. The radiometer has been applied to measurements of ultraviolet radiation and to that of short Hertzian waves (wave length one to two millimetres).

The explanation of the radiometric action has presented a problem of considerable interest. The question arises whether the rotation of the vanes may be caused by the direct impact of the radiation, somewhat as the rotation of a cup anemometer is caused by the wind. This explanation has been disproved in several ways. If, for example, the vanes are made of transparent material and blackened on the back face, they move toward the direction from which the light comes. The ordinary radiometer effect appears to be caused, therefore, by stresses set up in the gas. As the pressure of the gas is reduced, the rotation increases to a maximum and then decreases. Even in a very high vacuum, however, a small effect persists, directed away from the light. The magnitude of this residual effect agrees with the value as calculated from the electromagnetic theory of light, which predicts a small pressure because of incident radiation.

The ordinary radiometric action in the presence of gas has been rather definitely shown to be a consequence of the creep of the gas over the unequally heated surface of the vanes near their edges, as was suggested by J. C. Maxwell in 1879. The gas creeps toward the more heated part of the vane's surface and produces there a slight condensation of the gas and an increase in its pressure; the inequalities of pressure thus created give rise to a reverse flow in the surrounding gas, but this flow is hindered by viscosity, so that some inequality of pressure persists and forces the vane back. This phenomenon of gas behaviour, known in other occurrences as thermal transpiration (with "transpiration" used in the pure sense of leaking), is discussed in E. H. Kennard, *Kinetic Theory of Gases*, 1st ed., pp. 333-37 (1938).

RADIO RECEIVER. The two principal parts of a radio system are the transmitter and receiver. The waves radiated from transmitting antennas set up voltages in a receiving antenna, so that the first function of a receiving set is to select the signal desired. This must then be amplified and further modified so that a faithful reproduction of a program can be produced by the loud-speaker. Although a modern broadcast transmitter may have an output of 50 kw., often only a few microwatts from distant stations are available at the receiving antenna, principally because of the spreading out of the radio waves as they are propagated through space. A large amount of amplification is thus required in order to obtain a sound output of one watt, for example.

History.—The first demonstration of the production and reception of radio waves was made by Heinrich Hertz in Germany in 1887. His receiver consisted of an open wire loop with spheres attached to the ends to form a gap. The presence of the waves was "detected" by observing a spark set up in the sphere gap. Hertz was interested only in studying the properties of the waves and expressed no thought of practical application. It remained for Oliver Lodge to develop a system of wireless communication in England in 1894. The receiver included an antenna, tuned circuit, a detector consisting of a glass tube filled with metal filings called a "coherer" and a relay-controlled inker for recording Morse code. Lodge subsequently received several patents on radio apparatus—two of the better-known covering tuned circuits and loop antennas.

There was much activity in wireless telegraphy following Lodge's initial disclosures. Many new and improved types of

detectors or "cymoscopes" were invented. These included magnetic types by Guglielmo Marconi, Ernest Rutherford and others; electrolytic by F. K. Vreeland, R. A. Fessenden and Lee De Forest; and a wide variety of crystal detectors using carborundum, galena and iron pyrites.

The first electronic device to appear in radio receivers was the Zehnder trigger tube cymoscope in Germany in 1892. This was a glow tube in which the potential difference between anode and cathode was set to a value of several hundred volts. A discharge could then be initiated by impressing a radio signal between the pair of trigger electrodes with which the tube was provided.

The first thermionic electron tube for radio use was patented by J. A. Fleming in England in 1904. This was a vacuum diode detector tube, known as the Fleming oscillation valve. Its apparent advantage over other types of detectors was the ability to undergo mechanical shocks and static surges without "jarring out." Its inherent insensitivity to weak signals, together with the primitive status of manufacturing, limited its application.

The three-element vacuum tube was invented by De Forest in 1906. A receiver using an audion, as it was called, could deliver more power to an output device than was received from the antenna, so that it was operating in the dual capacity of detector and amplifier. Subsequent work showed that it could be used simply as a radio-frequency (R.F.) or audio-frequency (A.F.) amplifier, or even as a modulator. De Forest manufactured radio sets equipped with audions for several years. The audion was greatly improved by others during World War I and was manufactured in large quantities.

One of the most remarkable applications of the audion was to the feedback, or regenerative, circuit. In this, coupling was introduced between the plate and grid circuits such as to produce an appreciable increase in both the selectivity and sensitivity of the circuit. By providing adequate coupling, such a circuit could be made to oscillate continuously without benefit of external grid signal.

It is difficult to place proper priority for the invention of the feedback circuit. In 1913 Alexander Meissner was granted a patent on an oscillator in Germany and E. H. Armstrong presented a paper describing regenerative circuits. Other names associated with contemporary work were those of C. S. Franklin and H. J. Round in England and De Forest and Irving Langmuir in the United States. A four-way litigation initiated by Meissner, Armstrong, De Forest and Langmuir was decided finally in favour of De Forest by the supreme court of the United States in 1928, and it reaffirmed its action in 1934.

Considerable progress was made in the theory, construction and applications of vacuum tubes and their circuits between 1910 and 1920, much of it in connection with the World War I efforts and long-line carrier-current telephony. The greatest single impetus to be noted in radio history, however, was the introduction of radio broadcasting in 1921. This created a tremendous demand for receivers as transmitters were established throughout the world. The vacuum-tube receiving circuits were battery operated for the first few years, but rectifier-type power packs soon appeared for plate and grid supplies. These were followed almost immediately by the self-contained alternating-current sets, which were made possible by the development of tubes whose cathodes could be operated on alternating current without introducing excessive hum in the output.

The first broadcast signals were amplitude modulated (AM) exclusively, and many types of receiving sets were in use. Some of the commonest were: regenerative, superregenerative, reflex, tuned radio frequency, neutrodyne and superheterodyne. The superheterodyne came to be used almost exclusively for broadcast reception, although a few portable models employ tuned-radio-frequency circuits.

The difficulties of static elimination inherent in AM operation led Armstrong to develop frequency modulation (FM). Although he began work on the problem in 1914, his system was not perfected until 1933 and several more years elapsed before much use was made of it.

Modulated Waves.—It is impractical to transmit audible sig-

nals by wireless because the radiated output of an antenna depends upon its size expressed in terms of the wave length of the signal to be transmitted. Since the wave-length range is 3,720 to 37.2 mi. for the ordinary broadcast audio-frequency range of 50 to 5,000 cycles per second, it is only too obvious that not only would the necessary audio-frequency antennas be prohibitively large but there would also be the possibility of a 10,000 to 1, or 40 db., variation in the output over this 100-to-1 frequency range. Furthermore, only one station could be on the air at once in any given locality, since it would be impossible to tune out the unwanted signals. Thus, it is practical to transmit wireless signals only at the high frequencies known as radio frequencies.

The problem was easily solved in radiotelegraphy by the comparatively simple process of keying, or turning on and off, a high-frequency signal. However, it was necessary to devise a different method to transmit a "message" in the form of articulate speech or music. Such a method was found in the utilization of a high-frequency wave as a vehicle, or carrier, for the comparatively low-frequency message. The exact mechanism consists of modifying, or modulating, the carrier signal in some manner by the audio signal, the resultant radiated signal being known as a modulated wave.

Any high-frequency electromotive force, of a form denoted by the formula $e = E \cos(\omega t + \theta)$, is completely specified if the amplitude E , angular frequency ω and phase angle θ are given. An audio-frequency signal to be transmitted can be introduced into the given radio signal by causing it to modify any one of these functions, the three methods being known as amplitude, frequency and phase modulation, respectively. A fourth possible method involves breaking up the signal into pulses. However, this discussion will be limited to amplitude and frequency modulation since they are the most commonly used.

Amplitude Modulation.—If, in the general equation above, E is set equal to $E_0 + E_m \cos \omega_m t$, the result is

$$e = (E_0 + E_m \cos \omega_m t) \cos \omega_c t = E_0 (1 + m_a \cos \omega_m t) \cos \omega_c t$$

in which E_0 is the amplitude of the unmodulated carrier voltage; E_m is the amplitude of the modulating signal voltage; ω_m is the angular frequency of the modulating signal voltage; ω_c is the angular frequency of the carrier voltage; and m_a is the amplitude modulation index (E_m/E_0). Applying a trigonometric identity now gives

$$e = E_0 \cos \omega_c t + E_s \cos(\omega_c + \omega_m)t + E_s \cos(\omega_c - \omega_m)t$$

in which E_s is the amplitude of the side bands ($m_a E_0/2$), where $(\omega_c + \omega_m)$ is the angular frequency of the upper side band and $(\omega_c - \omega_m)$ is the angular frequency of the lower side band.

This is the equation commonly used for an amplitude-modulated signal, which consists of a carrier term together with upper and lower side bands for each component of the modulating signal. In order to transmit, at a carrier frequency of 1,000 kc., music of regular broadcast quality covering a frequency range up to 5 kc., a band width of 10 kc., or 995 to 1,005 kc., is required. Since this involves a maximum frequency variation of only 0.5% on either side of the carrier frequency, no special difficulty is involved in the design of the equipment.

The process of removing the original signal from the modulated one at the receiver is known as demodulation. As an illustration of this, assume the response curve of some nonlinear device, such as a crystal or vacuum tube operating over the curved portion of its characteristic, to be given by

$$i = a_1 e + a_2 e^2$$

Substitution in the equation for an amplitude-modulated signal and application of trigonometric identities yields, in addition to radio-frequency terms, an audio-frequency response given by

$$2a_2 E_0 E_s \cos \omega_m t = a_2 m_a E_0^2 \cos \omega_m t$$

and

$$a_2 E_s^2 \cos 2\omega_m t = \frac{a_2 m_a^2 E_0^2}{4} \cos 2\omega_m t$$

The former corresponds to the original signal to be transmitted; the latter to second harmonic distortion.

Frequency Modulation.—This is accomplished by introducing into the frequency of the signal to be radiated a variation about the carrier frequency that is proportional to the modulating signal. This gives, after some manipulation, for the general equation for a frequency modulated voltage,

$$e = E_0 \sin(\omega_c t + k_f \frac{E_m}{\omega_m} \sin \omega_m t)$$

in which k_f is the ratio of the maximum variation in frequency to the maximum strength of the modulating signal.

This can be expanded to yield a carrier and an infinite number of pairs of side bands whose amplitudes are expressed in terms of Bessel functions (see FUNCTIONS, SPECIAL). Although from a practical standpoint it is only necessary to pass a limited number of side bands, the required band width is much greater than that for the AM signal, which requires only one pair of side bands for each component of the modulating signal.

In particular, it has been found possible to transmit a maximum audio frequency of 7.5 kc. within a band width of 200 kc., which shows that FM transmission is not practical in the regular band of 550 to 1,500 kc. allocated for AM broadcast. A special band of 88 to 108 mc. is used for the stations being spaced 200 kc. apart.

TYPES OF RADIO RECEIVERS

Regenerative Receivers.—One of the first circuits in common usage is shown in fig. 1. In this the single tube acted as both radio-frequency amplifier and detector. The input circuit was tuned by means of the variable air condenser and taps on the vario-

FIG. 1.—SINGLE-CIRCUIT REGENERATIVE RECEIVER

coupler tuning coil, and the amount of feedback was controlled by rotating the tickler coil. This circuit was especially common in home-built sets, principally because of its simplicity. Other types of regenerative receivers were the two- and three-circuit, tuned plate, Cockaday, etc. Most of them had a tendency to oscillate and to act as a radio transmitter while being tuned. The radiated output would combine with other signals present to produce obnoxious squeals and whistles in neighbouring sets. This, together with a demand for more selective receivers as the number of broadcast transmitters with closer frequency allocations increased, eventually limited the regenerative receiver to long-wave and marine use.

Superregenerative Receiver.—The selectivity and sensitivity of a regenerative receiver increases rapidly with the coupling and resulting approach to the condition for sustained oscillation. Armstrong in 1922 first described a circuit for taking advantage of this by superimposing a supersonic signal upon the received signal in a manner such as to prevent the circuit from oscillating at a high frequency. This principle is used in the superregenerative receiver, which is characterized by extremely high sensitivity. Because of poor quality of output, its use is limited principally to short-wave reception in police and radio amateur sets.

Reflex Receiver.—Reflex action consists of feedback action

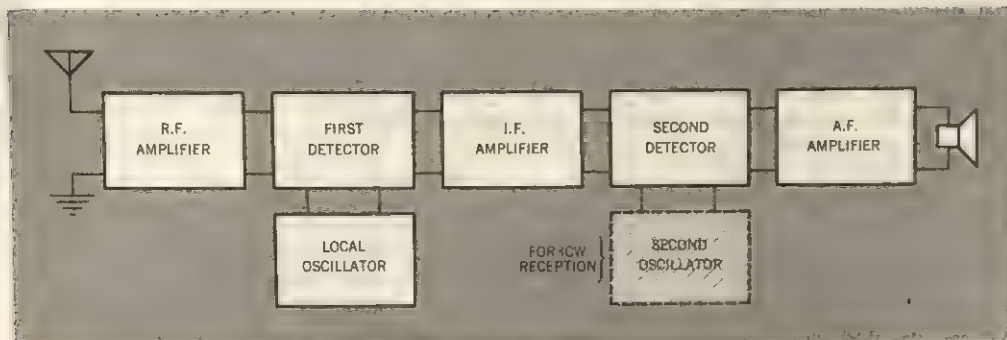

FIG. 2.—BLOCK DIAGRAM FOR SUPERHETERODYNE RECEIVER

between the plate circuit of one tube and the grid circuit of the preceding tube. In the reflex receiver, the antenna signal was first amplified by one stage of tuned radio frequency (T.R.F.) and then applied to the grid of the detector tube. The audio-frequency output of the latter was then fed back to the grid of the first tube by means of an audio-frequency transformer, the headset or loud-speaker being connected in the plate circuit of that tube. Thus, the first tube acted simultaneously as a radio-frequency and audio-frequency amplifier, to give sufficient output to operate a small loud-speaker upon occasion. This was an important consideration in the days of high-priced tubes, parts and batteries. Poor selectivity was the principle factor which brought about an early obsolescence.

Tuned-Radio-Frequency (T.R.F.) Receiver.—It was found that an increase in both sensitivity and selectivity could be obtained by introducing one or more stages of the tuned-radio-frequency amplification preceding detection. However, the plate-grid capacitances in triodes created a tendency for the circuit to oscillate. Although a limited amount of feedback action was desirable, it was necessary to control it carefully in order to prevent oscillations. Bridge circuits for accomplishing this were developed by C. W. Rice and L. A. Hazeltine. A set utilizing the last was known as the neutrodyne receiver, considered to be the last word in receivers until superseded by the superheterodyne.

Some of the weaknesses inherent in early types of tuned-radio-frequency receivers were separate tuning for each stage and non-uniform neutralization, sensitivity and selectivity over the broadcast band. The first was removed by gang tuning and the need for neutralization by use of screen-grid tubes, but the problem of varying sensitivity and selectivity remained in tuned-radio-frequency receivers. As a result, this type is used in only a few portable broadcast receivers and certain isolated applications where the selectivity requirements are not too stringent.

Superheterodyne Receiver.—A circuit which gave uniform performance over a wide range of station frequencies was developed by Armstrong while working in France during World War I. This made use of the heterodyne principle, which consists of combining two frequencies to give a different frequency. It had been introduced by Fessenden of the University of Pittsburgh in 1913, to convert radio-telegraph signals into interrupted audio-frequency code signals.

In the Armstrong superheterodyne receiver, or supersonic heterodyne receiver as it was called first in England, the incoming signal is combined with the output of an oscillator to produce a given supersonic frequency, called the intermediate frequency (I.F.). The latter is then amplified by means of one or more tuned stages, demodulated to give the required audio-frequency signal, amplified and finally fed into a loud-speaker. The selection of the particular station to be received is accomplished by adjusting the oscillator frequency so that the difference between it and the carrier frequency of the re-

ceived station is equal to the intermediate frequency. Since the major part of the amplification is in the intermediate-frequency amplifier, both the selectivity and sensitivity of the set are essentially independent of the original station frequency. The advantages of the superheterodyne receiver were quickly recognized, but since the early sets required eight or ten expensive battery-operated tubes its use was limited to the more expensive models. Within 20 years, however, it had

almost completely supplanted other types of broadcast receivers.

The accompanying block diagrams show the principal features of typical modern receivers. Starting at the input terminals, the signal is first amplified with one stage of tuned radio frequency in order to provide initial selectivity and thus to reduce so-called image and cross-modulation effects and mixer tube noise. The tuned-radio-frequency amplifier and local oscillator circuits are gang-tuned with a single control.

The mixer, converter or first detector tube, as it is called, changes the carrier frequency of the signal to the intermediate-frequency value. This was originally taken as 50 kc., but was later increased to 130-175 kc. Later it was further increased to 450-480 kc., with a tendency to standardize at 455 kc. in order to accommodate multiband receivers.

The intermediate-frequency amplifier usually consists of one or two transformer-coupled stages. The primaries and secondaries are permanently tuned, aside from small "trimmers" which are used for alignment purposes. The major portion of the high-frequency gain occurs in the intermediate-frequency amplifier. Remote cutoff pentodes are used to permit automatic gain control.

The function of the second detector is to convert the modulated intermediate-frequency signal into audio frequency. Square-law detection by means of a triode was used originally. This is preferable for weak signals, but since the percentage of second harmonic distortion increases rapidly with signal strength and percentage modulation, linear detection came to be used.

Among the advantages of high-level linear detection are the elimination of one stage of audio-frequency amplification, low harmonic distortion, reduction in tube noise and a lowering in cost of power pack filter because of the higher permissible hum.

The process of linear detection is essentially one of rectification and can be accomplished with either diodes or suitably biased grid-control tubes. Duplex tubes are often used, one part feeding into the audio-frequency amplifier, the other into the automatic volume-control system.

The audio-frequency amplifier may consist of one stage of voltage amplification and a power stage which utilizes two power pentodes in push-pull, when considerable output is demanded.

Automatic volume, or gain, control (AVC) was one of the most important developments in radio receivers. Its principal purpose is to maintain constant detector input. In this way the output of the receiver is unaffected by the strength of incoming signals. In brief, automatic volume control is accomplished by introducing an extra bias in the remote-cutoff tubes in the tuned-radio-

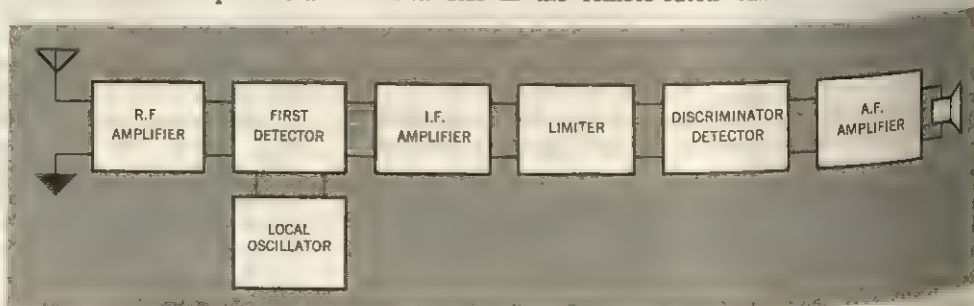

FIG. 3.—BLOCK DIAGRAM FOR FM BROADCAST RECEIVER

frequency and intermediate-frequency stages, which increases with the carrier input to the second detector. This automatically adjusts the gain of those stages so as to maintain nearly constant detector input as long as the incoming antenna signal exceeds a minimum threshold value.

The output of a receiving set is adjusted to suit the listener by means of a volume control, consisting of a potentiometer in the audio-frequency amplifier.

Since the sensitivity of the ear varies with frequency, some volume controls also include fixed coils or condensers such that the quality of the loud-speaker output will appear to be independent of intensity.

The purpose of the tone control is to allow the listener to vary the relative intensity of the high and low tones. The circuit for doing this often consists of a variable resistance connected in series with a fixed capacitor, its effect being to emphasize the bass notes by de-emphasizing the treble.

Receivers for FM Reception.—The block diagram in fig. 3 is schematic for a typical receiver designed for use in the 88- to 108-mc. FM broadcast band. In commercial sets, however, a converter stage replaces the local oscillator and the first detector mixer. Except that the intermediate frequency is 10.7 mc. instead of 455 kc., a change made necessary by the greater band-width requirements of FM, the functioning of the set is similar for receiving both AM and FM up to and including the I.F. amplifier. The output of the I.F. amplifier, however, instead of feeding into the detector as for AM, first goes through a limiter which levels off

approval became effective June 1, 1961. Previously, FM multiplexing had been utilized for several years by at least 200 stations in the U.S. as a means of broadcasting background music on a

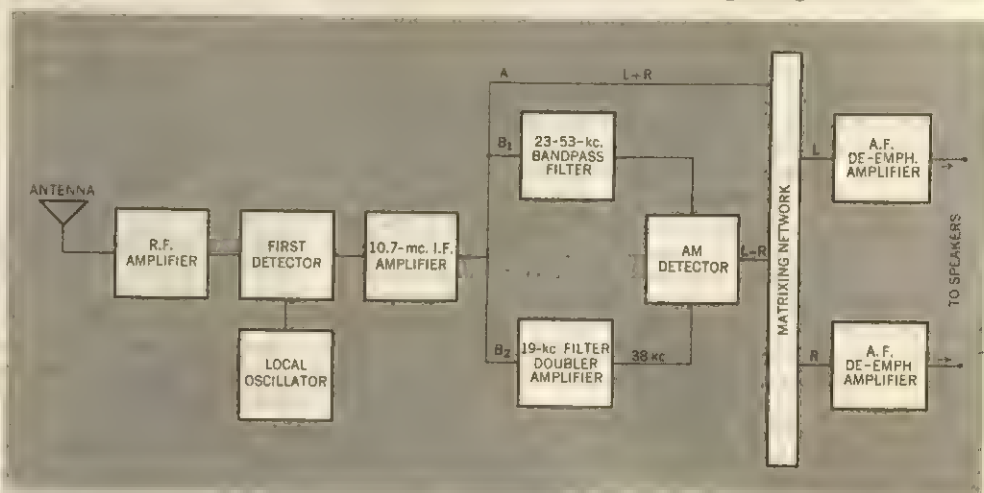

FIG. 5.—FUNCTIONAL DIAGRAM FOR STEREOPHONIC RECEIVER

FIG. 4.—FREQUENCY SPECTRUM FOR FM STEREOPHONIC BROADCAST

the signal to a fixed amplitude of a few volts. This is very effective in eliminating interference as well as noise due to static, ignition systems, etc., since it is estimated that only about 3% of such disturbances are of a frequency-modulation character. This results in a possible gain in the signal-to-noise ratio of as much as 30 db. by the use of FM.

The first step in the demodulation process is to convert the output of the I.F. amplifier into an AM signal. This is done with a frequency-sensitive circuit called the discriminator. A typical arrangement consists essentially of a coupling transformer with tuned primary and secondary. The desired shape of its frequency response curve is obtained by using coupling slightly less than critical. The output of the discriminator is fed into a detector and the resulting audio signal is further amplified and fed into a loud-speaker as in AM reception.

Receivers for Stereophonic Reception.—The U.S. Federal Communications commission on April 19, 1961, approved a multiplex system for broadcasting stereophonic programs in a single band in the regular 88 to 108 mc. FM broadcast spectrum. The

rental basis to factories, restaurants and other commercial establishments. The approved system for stereophonic broadcast made provision for continuing this special service, although—as in the case of monophonic broadcasting—background music signals are filtered out in home receivers.

The specified FM spectrum for stereophonic broadcasting, including the optional band for transmitting background music, is shown in fig. 4. With appropriate changes in the co-ordinates, this diagram also can be used to represent the upper sideband halves of both the radiated and received signals or, by omitting the background music portion, it can be used to portray the output of the FM limiter-detector stage in a stereophonic home receiver.

The transmitted signal consists of a main carrier that has been frequency-modulated as follows: (1) up to 90% (75 kc. constitute 100% modulation in FM broadcast) by $L + R$, the sum of the left- and right-hand audio signals; (2) 8% to 10% by a 19-kc. pilot carrier; (3) up to 90% by a 38-kc. subcarrier which has been amplitude-modulated, with carrier suppressed, by $L - R$, the difference between the left- and right-hand audio signals; and optionally, (4) up to 10% by a 67-kc. subcarrier amplitude-modulated by background music whose upper limit has been set at 8 kc. The standards of performance are the same as for monophonic FM broadcasting.

The principal functions that must be performed by a stereophonic home receiver are portrayed in fig. 5. The first four sections in this are essentially the same as would be found in a similar diagram for a monophonic receiver, including 10.7 mc. for I.F. amplification. It is principally in the I.F. amplifier that background-music signals are filtered out in both monophonic and stereophonic home receivers; a specially adjusted receiver must be used to detect and amplify the background-music signal.

Starting with the output of the I.F. amplifier in fig. 5, channel A accepts and transmits $L + R$ to the matrixing network, a network whose output is a linear combination of two or more input signals. Channel B_1 accepts the 38-kc. subcarrier that is amplitude-modulated by $L - R$. Channel B_2 accepts the 19-kc. pilot carrier, doubles its frequency and amplifies it so that it can replace the 38-kc. subcarrier that was suppressed in the transmitter. The outputs of B_1 and B_2 are then applied to an AM detector which delivers $L - R$ to the matrixing network.

The output of the matrixing network consists of the sum and difference of its two inputs, to give $(L + R) + (L - R) = 2L$, and $(L + R) - (L - R) = 2R$, respectively. After de-emphasis and amplification, these are fed into two loud-speakers so arranged as to give the proper stereophonic effect.

A stereophonic receiver can ordinarily be used for monophonic FM reception, although some interference may be heard if the received signal happens to include a background-music subcarrier

that is at some point in the range of 20–53 kc. If a stereophonic signal is picked up by a monophonic receiver, a true monophonic reproduction, consisting of L + R, will be heard; the effect is the same as if two microphones were used in a monophonic broadcast. This is the reason for using L + R in place of either L or R as one of the original modulating signals for stereophonic broadcast. It is necessary to use an adaptor, as well as an additional amplifier and loud-speaker, with a monophonic receiver in order to obtain stereophonic reproduction.

Transistor Receivers.—The development of the transistor made it possible to construct a very small portable radio receiving set. In effect, the transistor permits the use of certain elements whose size is more commensurate with the amounts of useful power associated with the various parts of the receiver. This applies particularly to the replacement of thermionic vacuum tubes by transistors, since the latter require no cathode heating power. This removes the necessity of providing filament transformers and sufficient tube radiating surface to dissipate the cathode power.

RADIOSONDE, an instrument sent aloft, attached to a freely rising balloon, for the purpose of obtaining information on the temperature, humidity and other properties of the upper atmosphere. It includes a radio transmitter which sends down signals representing the numerical values of these properties. See UPPER AIR SOUNDINGS. (W. E. K. M.)

RADISCHEV, ALEKSANDR NIKOLAEVICH (1749–1802), Russian author, whose *Puteshestvie iz Peterburga v Moskvu* (1790; *A Journey from St. Petersburg to Moscow*) founded the revolutionary tradition in Russian literature and thought. The son of a nobleman, he was born on Aug. 31 (new style; 20, old style), 1749, in Moscow, and brought up at Ablyazo, Saratov province. Educated in Moscow (1757–63), at the St. Petersburg Corps of Pages, and at Leipzig, where he studied law (1766–71), he served under the minister of justice, as military procurator at the war office (1773–75), and at the Imperial College of Commerce (1777–90).

In 1773 he translated the abbé Mably's *Observations sur l'histoire de la Grèce* (1766), and, in a footnote to Mably's attack on Alexander the Great as a dynastic conqueror, made sharply critical comments on autocracy. His first original work, *Dnevnik odnoy nedeli* (written 1773), the diary of one week in the life of a "man of feeling," introduced Rousseau's cult of sentiment to Russian literature. A discourse on patriotism (1789) was criticized for its radicalism; and his biography of a college friend, Fedor Ushakov (d. 1770), one of the earliest intimate biographies in Russian, contained condemnations of political tyranny.

In *A Journey from St. Petersburg to Moscow*, he attacked all aspects of Russia's social and political order: the serfdom of the peasants, imperial tyranny, and the censorship. In an ode to liberty (*Vol'nost'*, written 1781–83; partially included in the *Journey*) he praised the English Revolution of 1688 and the American Revolution, and called on his countrymen to take arms against "the predatory wolf" (i.e., the tsar). Arrested (June 30, 1790) by order of Catherine II, he was imprisoned in the Peter and Paul fortress, and was sentenced to death, but was later reprieved and exiled to Siberia, where he remained until 1797. He was then allowed to settle on his estate at Nemtsovo, near Malo-Yaroslavets, and while there wrote the mock-heroic ballad, *Bova*; an ambitious "Song of History"; and other poems. Pardoned by Alexander I, in 1801 he became a member of the legislative commission under

Count Zavadovsky, and as well as helping to draft several liberalizing social and constitutional statutes, set forth his own plans for reform in memoranda on legislation and the civil code. Opposition, even from his friends, to his radical views on the freedom of the individual, free speech, and the canon law, and realization that the promised liberal revolution was not being achieved, led to increasing despondency, and on Sept. 23, 1802, he took poison, dying at 1 A.M. on Sept. 24 (N.S.; 12, O.S.).

BIBLIOGRAPHY.—*A Journey from St. Petersburg to Moscow* (ed. with introduction by A. Herzen, London, 1858; new translation, 1958) was first republished in Russia in 1905, in a collected edition of Radischev's works, 2 vol. (1905–07). His complete works were ed. by the Academy of Sciences of the U.S.S.R., 3 vol. (1938–52). See also A. S. Pushkin, *A. Radischev* (1836); D. D. Blagoi, *Radischev* (1949); G. P. Makogonenko, *Radischev i ego vremya* (1956); D. M. Lang, *The First Russian Radical, A. Radischev*, with bibliography (1959). (D. D. Bl.)

RADISH, *Raphanus sativus* (family Cruciferae), an annual or biennial grown for its large, succulent root. The edible part of the root, together with some hypocotyl, form a structure varying in shape, among varieties, from spherical through oblong to long cylindrical or tapered. The outside colour of the root varies from white through pink to red, purple and black; the size of the edible part varies from a few grams in the most popular early American and European varieties to two pounds or more in the late Japanese field type of radish, or daikon. As generally grown, flower stalks form the first season, bearing white or lilac-veined flowers. The seeds are borne in a spongy, nondehiscent, beaked pod called a silicle.

The small, quick-growing spring varieties have a mild, crisp, moderately firm flesh, and are quite perishable. The large, slow-growing summer and winter types have pungent, firm flesh. Winter varieties can be stored through the winter. The common radish is probably of oriental origin. *R. raphanistrum* is a wild radish found along the Mediterranean. The rat-tailed radish (*R. sativus*, var. *caudatus*) has no enlarged root, but bears enormous seed pods 8–12 in. long which are eaten fresh or pickled. *R. sativus* (var. *longipinnatus*) produces deeply pinnate leaves up to two feet long; the roots are large, firm and are grown as a winter radish. This type is much grown in the orient and is generally known as Chinese radish. (V. R. B.)

RADIUM, the most familiar of the natural radioelements, is a metallic element belonging to the alkaline-earth group, of which it is the heaviest. The name, derived from the Latin *radius* ("ray"), originally applied only to the first discovered and most important isotope of the element, that of mass number 226, but is now used as a general name for the element.

Radium was discovered in 1898 by Pierre Curie, Marie Curie and an assistant, G. Bémont, at the Sorbonne in Paris. Mme. Curie had observed that the radioactivity of pitchblende, an ore of uranium, was several times that of the uranium it contained. By chemical separation of the constituents of the mineral, two highly radioactive elements—polonium and radium—were discovered. Prior to this discovery, it had been customary to discard the residue of pitchblende after extraction of uranium.

Radium was found to adhere closely to the common element barium, which it followed in the chemical treatment of the ore, indicating a very close chemical relationship of the two elements. Only after developing a complicated fractional precipitation procedure could the two elements be separated. Then, in 1902, Mme. Curie was able to prepare a pure salt of radium by working up several tons of pitchblende residues. The same general method of extracting radium is used commercially, a tribute to the genius of this pioneer in radiochemistry.

The pure element was first prepared in 1910 by Mme. Curie and A. Debierne; it is a shiny white metal.

The symbol of radium is Ra; atomic number 88; atomic weight 226.

Isotopes and Radioactive Properties.—Several isotopes of radium, all radioactive, are known. Only Ra^{226} is stable enough to permit its isolation in visible and weighable amounts, and the name "radium" often refers simply to this isotope. Its half life is approximately 1,620 years, and it disintegrates with the emis-

sion of alpha particles. It is a member of the uranium, or radium, family of natural radioelements, following ionium in the series. Its immediate transformation product is radon, a rare gas of 3,825-day half life, which in turn changes into a series of shorter-lived radioelements, radium A, B, C, C' and C". It is rarely encountered in a radioactively pure form, for immediately after purification from its disintegration products they rapidly grow in again. Radium C emits penetrating gamma rays, so that, although radium itself emits only small numbers of gamma rays of low penetrability, a sample which has been sealed up to prevent loss of the gaseous radon is a source of strong gamma radiation. About a month is required for the gamma activity to reach its maximum, or equilibrium, intensity. The end product of the short-lived descendants of radium is radium D, which is also radioactive, and from this grow radium E and polonium, or radium F. Since the half life of radium D is 20 years it comes to equilibrium slowly in radium preparations.

The half life of radium is so great that it cannot be determined by directly observing the decay, and recourse must be had to indirect methods. Most of these involve the determination of the specific activity, or the number of disintegrations per unit weight in unit time. This can be done by counting the alpha particles emitted in a measured interval by a sample of known weight. The first measurements were done by visual counting of the scintillations produced by the impact of the particles on a zinc sulfide screen, while later experimenters have used electrical detection and counting instruments. Since alpha particles are helium nuclei, measurement of the rate of helium generation by radium provides another means of determining the specific activity. The half life also can be calculated from the rate of growth of radium in a sample of purified ionium relative to the amount in equilibrium with the same quantity of ionium in ancient and intact uranium minerals. Finally, from the equilibrium ratio of radium and uranium in such minerals the half life of radium can be calculated if that of uranium is known independently. The specific activity is close to 3.61×10^{10} alpha disintegrations per second per gram, whence the half life is 1,620 years. The disintegration rate of radium formed the basis of a standard unit of radioactivity, the curie, originally a rate of disintegration equal to that of a gram of radium. Now, a curie of any radioelement is by definition that amount undergoing 3.7×10^{10} disintegrations per second.

In the thorium series of radioelements occur two radium isotopes, mesothorium I (Ra^{228}) and thorium X (Ra^{224}), the former a beta emitter of 6.7-year half life and the latter an alpha emitter of 3.64-day half life. One of their descendants, ThC'' , emits gamma radiation even more penetrating than that of RaC , and as a result of the complex sequence of half lives the gamma activity of freshly purified mesothorium increases for about four years and then decays steadily. A fourth isotope, actinium X (Ra^{228}), occurs in the actinium series and is an alpha emitter of 11.7-day half life. (See RADIOACTIVITY.)

Several artificial radioactive isotopes of radium are also known. (See NUCLEUS.)

Natural Occurrence.—Although the half life of radium, 1,620 years, is long with respect to human experience, it is infinitesimal in the geological time scale, and any radium present at the time of the formation of the earth has by now completely disappeared. It is only because a new supply of the element is continually being generated by the disintegration of uranium that any is found at the present time, and its distribution in nature is practically identical with that of uranium. There is a constant ratio between radium and uranium, 0.00000034, in all sufficiently old minerals in which radioactive equilibrium has not been disturbed by weathering or leaching. In altered minerals the radium is generally relatively lower because of the greater solubility of its oxide. Springs, rivers, sea water and the ocean sediments contain small amounts of radium. Uranium, and consequently radium, are widely distributed in minute traces in nearly all common rocks, both igneous and sedimentary, the average concentration of radium in the earth's crust being about 1 part per 1,000,000,000,000. The bulk of the earth's radium is so accounted for; but in this form it is, of course, commercially unavailable. Only in uranium minerals is

radium present in high enough concentrations to make its extraction feasible, and even the richest ores contain only about $\frac{1}{4}$ g. of radium per ton. Most deposits contain smaller amounts; and some which contain as low as 1% of uranium, or 1 g. of radium in 300 tons, have been exploited for the latter.

Radium was discovered in the mineral pitchblende, an oxide of uranium, which had been mined since about 1840 at Joachimsthal, Czech., for its uranium content. More extensive pitchblende deposits were later found at Katanga in the Belgian Congo and at Great Bear lake and Beaverlodge lake in Canada. Second in importance as a radium source is carnotite, a double vanadate of uranium and potassium found principally as a yellowish impregnation of sandstone in the western United States. Altogether several dozen different radium-containing minerals are known, and deposits of varying extent are found in many other places; some of these have been worked from time to time for radium. The increased importance of uranium, as a source of atomic energy, has resulted in intensive prospecting and the discovery of many more such deposits. (See URANIUM.)

Mesothorium is obtained principally from monazite, a mixed phosphate of thorium and rare earths occurring frequently in alluvial sands. (See THORIUM.) Thorium X and actinium X occur naturally in thorium and uranium minerals, respectively, but are usually obtained from their parents rather than from natural sources.

Industrial Production.—For a number of years following its discovery the only important source of radium was the Joachimsthal mines, operated by the Czechoslovakian government. Later some radium was produced in other European countries. The United States became the first major producer and from 1913 to 1923 was the chief world supplier, with carnotite from the western states being extracted principally at Denver, Colo., and Pittsburgh, Pa. The rich Belgian Congo pitchblende deposits were discovered in 1913; and the refinery at Olen, Belg., began production in 1922, immediately dominating the world market. The extensive Canadian deposits were discovered in 1930; and the refinery at Port Hope, Ont., started producing radium in 1933. In the late 1930s the world market was divided between the Belgian and Canadian producers on a 60:40 basis by a cartel agreement. After Belgium fell to the German army in 1940, the Congo ores were shipped to the United States and Canada for refining. Following World War II, radium-bearing residues from these ores were shipped to Olen for extraction of radium.

The following is a typical procedure for the commercial production of radium from pitchblende. The ground ore is digested with a mixture of nitric and sulfuric acids to which a little barium is added to act as a carrier for the radium. The uranium dissolves, and an insoluble residue of radium, barium and lead sulfates and siliceous gangue remains. This is separated by filtration and boiled with sodium hydroxide solution to leach out the lead sulfate and some of the silica. The residue is then autoclaved with sodium carbonate solution to convert the barium and radium sulfates to carbonates, which are dissolved in hydrochloric acid. After filtering off the remaining silica, the barium and radium are again precipitated as sulfates and converted to carbonates to effect a purification. The carbonates are now dissolved in hydrobromic acid and the bromides subjected to an involved fractional crystallization process. Since radium bromide is somewhat less soluble than barium bromide, the crystals are enriched in radium. After ten recrystallizations the ratio of radium to barium in the head crystals is changed from a few parts per 1,000,000 to a few parts per 1,000. At this stage, the bromides from several batches are accumulated, purified again and subjected to further crystallizations until radium of the desired purity, usually 95% or 99%, is obtained. This is sealed into small glass tubes to be measured and sold.

Variations in this process are dictated by differences in the nature and quality of the ores found in different locations. Canadian pitchblende contains considerable native silver, which is recovered by roasting the ore with sodium chloride to convert the silver to its chloride and subsequently leaching the latter out of the sulfate residue with sodium thiosulfate solution. With carnotite, the

treatment can be altered by leaching the ground ore with hydrochloric acid to dissolve the radium, uranium and vanadium away from the siliceous matter before adding sulfuric acid. The sulfate precipitate can alternatively be heated with charcoal to reduce the sulfates to sulfides, which dissolve readily in hydrochloric acid. In the fractional crystallization the chlorides are often used instead of the bromides.

Newly developed methods for separating radium from barium involve cation exchange resins and precipitation from homogeneous solution.

Radium was originally interchanged freely among scientific and medical investigators, but when it became an item of commerce it became extremely expensive. However, as new and richer sources have become available, the price has steadily fallen. Typical market prices per gram were \$10,000 in 1904, \$80,000 in 1912, \$120,000 in 1915, \$135,000 in 1918, \$90,000 in 1920, \$70,000 in 1923, \$50,000 in 1929, \$25,000 in 1936, \$20,000 in 1941, \$25,000 in 1946, \$20,000 in 1950, \$16,000 in 1953 and \$15,000 in 1957. The total world production in grams was approximately 50 by 1916, 300 by 1925 and 1,000 by 1940. Production was greatly accelerated during and shortly after World War II, but was declining in the 1960s because of the competition of substitutes.

Chemical Properties.—Of the 88 electrons of the radium atom, the first 86 are strongly bound, whereas the outer two are readily lost leaving a divalent cation of noble gas structure. This property classifies it among the alkaline-earth elements, which include, in order, magnesium, calcium, strontium, barium and radium. There is a general gradation of properties in going from the lighter to the heavier members of the group, and radium continues this trend. It is very similar to barium, all of its known compounds being isomorphous with the corresponding barium compounds and differing so little in properties as to make the separation of the two elements a matter of great difficulty. The chemistry of radium, is, therefore, well understood.

Radium is divalent in all of its compounds. The sulfate, RaSO_4 , is the most insoluble sulfate known and for this reason is important in the separation of the element from its ores. However, it is only because lead sulfate is also precipitated from the solution of the ore that quantitative precipitation of radium is obtained, for the amount of radium sulfate present is far too low to precipitate by itself. This principle, whereby an element present in quantity too small to permit manipulation by itself is caused to undergo certain chemical reactions by the presence of a larger quantity of a similarly behaving element, is called "carrying" and is important both in the isolation and in the chemical study of radium. The nitrate, $\text{Ra}(\text{NO}_3)_2$, chloride, RaCl_2 , and bromide, RaBr_2 , are soluble in water but highly insoluble in concentrated solutions of the corresponding acids, and are consequently of use in the purification of radium, including its separation from the last traces of barium. The chloride and bromide crystallize as hydrates, $\text{RaCl}_2 \cdot 2\text{H}_2\text{O}$ and $\text{RaBr}_2 \cdot 2\text{H}_2\text{O}$, but form the anhydrous salts on heating. The hydroxide, $\text{Ra}(\text{OH})_2$, is the most soluble of the alkaline-earth hydroxides. The carbonate, RaCO_3 , is insoluble in water but soluble in acids and the sulfide, RaS , is soluble in water.

Metallic radium melts at approximately 700°C . and has high chemical reactivity. It dissolves in water with vigorous evolution of hydrogen and darkens in air with the formation of the nitride. It is prepared by electrolysis from an aqueous solution of the chloride into a cathode of mercury, followed by volatilization of the mercury in a stream of hydrogen.

The optical spectrum of radium is similar to that of the other alkaline-earth elements, consisting of comparatively few relatively strong lines. The ordinary compounds of radium are all colourless but become coloured upon standing as a result of the continual bombardment by radioactive particles. Glass containers of considerable quantities of radium also become coloured, and sizable preparations can be seen to glow in the dark. Those properties are not peculiar to radium but are common to all strongly radioactive substances.

Analytical Methods.—The assay of radium is generally made not by the usual chemical procedures, such as weighing, but by methods based on its radioactivity. Strong samples, such as those

for medical and radiographical use, are assayed by their gamma radiation by means of an ionization chamber and electrometer. The sample must be sealed for at least a month before the measurement so that the equilibrium quantity of radium C is present. For calibration of the measuring apparatus, standard preparations of radium have been made. The primary international standard was prepared by Mme. Curie by precise weighing and has been preserved at Sèvres, France. Secondary standards, carefully checked against the international standard, are kept in the capitals of the principal nations. In using these standards allowance must be made for their decay, which amounts to 0.043% per year. Another assay method is the emanation technique, in which the gaseous radon generated by the radium sample in a measured time is collected in an ionization chamber and the intensity of its radiations measured. This method can be made extremely sensitive by electrically counting the individual alpha particles, and as little as 10^{-14} grams of radium can be so detected.

Uses.—The uses of radium all result from its radiations. The most important of these have been in medicine, principally for the treatment of cancer. For this purpose the element may be used directly, sealed in a tube, or the accumulated radon may be drawn off and compressed into a small capsule which may be used until it has decayed to a low intensity. (See RADIOLOGY.) Large amounts of radium have been employed for industrial radiography, particularly for the inspection of metal castings. Radium is mixed, in small concentrations, with a paste of zinc sulfide to make a luminescent paint for watch, clock and meter dials and signs which must be read in the dark. An intimate mixture of radium with beryllium is a moderately intense source of neutrons. Such neutron sources have been used extensively in scientific work and have found practical applications in well logging in geophysical prospecting for petroleum. Radium-bearing slime from uranium processing is used as a marking compound in oil-well casings.

Mention should be made of the hazards of handling radium, which result from the physiological effects of its radiations and which are enhanced by the gaseous nature of its decay product, radon. Before the dangers were recognized and adequate precautions taken a number of radium workers suffered serious injury or death. For physiological effects of radioactive substances see RADIOLOGY.

Mesothorium can be used in a manner similar to radium for all the purposes mentioned, but its greater expense and shorter lifetime limit its applications. It is superior to radium as a luminous paint activator because the intensity of its radiations increases for several years and thus compensates for the fatigue of the zinc sulfide. Except for scientific purposes, the other radium isotopes have no practical value.

For all the uses of radium, substitutes have become available. Artificial radioelements and high-voltage X-ray generators are supplanting radium in radiotherapy and radiography. Fluorescent paints activated by ultraviolet radiation are replacing radium paints in airplane panel meters. Cyclotrons and nuclear chain reactors provide much more intense neutron sources. Nevertheless, the use of radium is still important because of its special properties and its availability as a by-product of uranium.

RADNORSHIRE (SIR FAESYFED), an inland county of Wales, is bounded on the east by Shropshire and Herefordshire and on the west and north by Brecknockshire and Montgomeryshire. Its area is 470.7 sq.mi. (1,219.1 sq.km.).

Physical Features.—Most of the county exceeds 600 ft. (about 200 m.) above sea level, and half of it is more than 1,000 ft. (328 m.), reaching 2,166 ft. (711 m.) centrally in Radnor Forest. Only in the lower Wye Valley is there a small area below 300 ft. (about 100 m.). Because the general trend of relief is from north-east to southwest, the rivers Wye and Teme flow southeast in deep

valleys. The Lugg and Arrow flow east from Radnor Forest, while the Ithon drains the centre of the county south and then southwest to the Wye.

Geologically, the county is largely composed of Ordovician and Silurian rocks with igneous intrusions between Llandegley and Llanellwedd. Old Red Sandstone occurs in the east and south only. Recent alluvium lies in the lower river valleys; glacial drift is widespread.

Radnorshire has cool, damp summers and mild, wet winters, but relief creates surprising contrasts; the lower Wye Valley at 300 ft. can be 6° F (3.3° C) warmer than Radnor Forest at 2,166 ft., while rainfall averages 80 in. (2,032 mm.) annually in the high western hills compared with only 35 in. (889 mm.) in the low eastern valleys. The west of the county has poor, acid soils, peat soils developing on the wet, badly drained hilltops. On the Old Red Sandstone and alluvium soils are more fertile.

The original deciduous forests of the valleys have disappeared except from the hedges and steep river banks, and from the private and public parks and woods. The high hills are covered with rough fescue pastures, grading upward into heather moor or *Molinia-Nardus* moor. Below 1,000 ft. are mainly enclosed fields of grass, generally of *Agrostis* with rushes on fields which are difficult to drain. Only in the more fertile eastern valleys and in the Llandrindod and Llanellwedd areas is there better *Agrostis*-rye grass pasture. The only large areas of woodland are coniferous, planted in the Elan Valley by the Birmingham Corporation, and planted by the Forestry Commission on the northeastern slopes of Radnor Forest, in Coed Sarnau northeast of Rhayader, and (on a smaller scale) in the Edw Valley, totaling 20,000 acres.

History.—No archaeological finds proving permanent settlements by Stone or Bronze Age man have yet been made in Radnorshire, but burial mounds and finds of stone and metal artifacts prove their presence, at least, in the county. Later, iron-using Celts built simple hill forts on the lower hill slopes. Their descendants, the Ordovices, were subdued by the Romans between A.D. 50 and 100 and held in subjection for 300 years from forts linked by roads. One road is presumed to have crossed the country from south to north, and on it, c. A.D. 80, was built Castell Collen Fort near Llandrindod; another that followed the lower Wye Valley was guarded by the Gaer Fort near Hay. The Roman legions used these roads and forts to keep peace among the Ordovices and to carry metals to their ports and towns of south Wales. When the Romans withdrew late in the 4th century the Welsh tribes continued their pastoral life, but intertribal warfare made Radnorshire (then called Rhwng Gwy a Hafren, "the land between Wye and Severn") a cockpit between the rival princes of Powys and Brycheiniog for six centuries. Meanwhile, the Anglo-Saxons had crossed England, and late in the 8th century King Offa halted the Mercian struggle with the Welsh by building the boundary dike, which is still a conspicuous feature of the county between Knighton and Burfa.

The beginnings of Christianity in southeast Wales died after the Roman withdrawal, but the faith soon reentered southwest Wales by sea from western Gaul, which still remained in touch with Rome. Along the ancient tracks and the disintegrating Roman roads, Irish and Gallic immigrants carried the cults of SS. David, Teilo, and Padarn inland and eventually into Radnorshire where Glaschw became a "mother church" of David. Dedications to SS. Michael, Mary, and Bride, common in the area, only came with the Normans who, after the victory at Hastings in 1066, swept to the Welsh border and by 1100 had a castle at New Radnor. For a century the local Welsh fought the barons Mortimer and de Braose, who built many castles to help their campaigns. Already the Welsh Church was being organized on Latin lines, and Radnorshire became part of St. David's diocese and was divided into rural deaneries. Houses of almost all the monastic orders were then founded in Wales, and these included the Cistercian abbey of Cwmhir, reputed burial place of the last Llewelyn in 1282.

The conquest of Wales in 1283 by Edward I left Radnorshire as marcher land, and another 250 years of fighting was only ended by Henry VIII's acts of union in 1536 and 1542, joining the Mortimer and Warwick lordships to form the modern shire of

Radnor. The county's boundary has changed little since, and the Tudor hundreds are basically the five modern rural districts of Colwyn, Knighton, New Radnor, Painscastle, and Rhayader.

Apart from the Civil War, when the county took the Royalist side, religious and economic strife has most upset local peace since Tudor times. Nonconformity dates from the Commonwealth; Maesyrnon Baptist Chapel was built in 1696, and the Quaker Meeting House at Llandegley is even older. Methodism, too, was established early in the 18th century. In the 1840s grievances over turnpike tolls caused the Rebecca Riots (*q.v.*), and the local fondness for poaching led to serious affrays starting in 1856 and ending only in 1907. Poverty and retaliation against enclosures explain these savage outbursts. The Rev. Francis Kilvert (*q.v.*) began his *Diary* while curate of Clyro (a village near the borders of Brecknockshire and Herefordshire) from 1865 to 1872.

Population and Administration.—The administrative area is 470.7 sq.mi. and Radnorshire (pop. [1961] 18,431) is the most thinly populated county in England and Wales. Nearly one-third of the total live in the three urban districts of Llandrindod Wells, Knighton, and Presteigne; the rest live in the five rural districts. There are also 23 parishes. The county's population in 1801 was 19,135, rising to a maximum of 25,458 in 1841, since when there has been a slow decline, the result of agricultural depression and mechanization and migration to the coal fields and large towns.

Though Presteigne (*q.v.*) is still the county town holding the courts of quarter sessions, the administrative centre since 1889 has been Llandrindod Wells (*q.v.*) where the county council meets. Radnor is joined with the county of Brecknock for parliamentary purposes and returns one member.

The Economy.—Public administration, distributive trades, transport, building, and contracting employ the bulk of the workers of the county, which has no mines and has fewer than 100 quarrymen producing granite, gritstone, and limestone. The Forestry Commission employs a small number in planting conifers on poor land up to 2,000 ft. Farming is widespread, and by reason of the height of the land, its climate and comparative isolation, the breeding of sheep and store cattle is paramount. About two-thirds of the land is under grass and less than 10% under the plow. Many thousands of Welsh, Kerry, and Clun sheep (pure and crossbred) and large numbers of Hereford cattle are sold annually, especially at autumn sales inside and outside the county. Radnorshire is completely devoid of large-scale manufacturing, although each town has one or two small factories which help slightly to check rural depopulation, endemic in the county.

Tourism is of increasing importance, based on the beauty and solitude of the county and the fame of its streams among fishermen. The reservoirs in the Elan and Claerwen valleys, which supply water to Birmingham, are a great attraction for visitors. Birmingham Corporation owns more than 30 sq.mi. (78 sq.km.) of land from which water drains to the reservoirs. Llandrindod Wells, a spa and conference centre, and Knighton, a market town, lie on the Shrewsbury to Llanelli railway which crosses the county. Rhayader, a small resort and fishing centre, is on the trunk road from Worcester to Aberystwyth, and Presteigne is an old border town within easy reach of the Midlands.

RADOM, a town in the Kielce województwo (province) of Poland, lies about 64 mi. (103 km.) S of Warsaw by road. Pop. (1960) 130,116. Radom is first mentioned in the 12th century. In the 14th century the town was walled and obtained market privileges. After the third partition of Poland in 1795 it was seized by Austria. Under the Duchy of Warsaw, from 1809 to 1815, Radom was the capital of a department. After incorporation in 1815 into the Polish kingdom, dependent on Russia, it became

capital of a *guberniya* (Russian province). It returned to independent Poland in 1918.

Because of frequent war damage Radom has few old buildings, but both the old town and the 14th-century town are apparent from its street layout. It has a museum and theatre. Radom is on the Warsaw-Cracow road and railway and is a rail junction for Deblin on the Warsaw-Lublin line. It is an important industrial centre, whose manufactures include tanning and producing leather, tobacco, chemicals, glass, timber and paper, clothing, and food.

(T. K. W.)

RADON is the heaviest element of the noble gas group and is an important radioelement. Its atomic weight is 222, its chemical symbol is Rn and its atomic number is 86. The name radon is used either for the most important isotope, that of mass 222, or for the element as a whole, although for the latter purpose the name emanation (symbol Em) is sometimes preferred. Other isotopes are thoron (Tn, mass number 220) and actinon (An, 219). Thoron was discovered in 1899 by R. B. Owens and E. Rutherford, who observed that some of the radioactivity of thorium preparations can be swept away by a current of gas. Radon was similarly discovered in radium samples by F. E. Dorn in 1900, and actinon was found associated with actinium in 1904 by F. O. Giesel and A. Debiere.

Radon is the immediate product of the decay of radium and undergoes alpha disintegration with a half life of 3.825 days. It yields several short-lived radioelements called the active deposit because of their tendency to adhere to solid objects. Thoron and actinon have similar properties, but because of their short half-life periods, 51.5 and 3.92 seconds respectively, they are of less importance than radon. (See RADIOACTIVITY; RADIUM.)

Because of its transient existence, radon is found only in conjunction with a source of radium. The atmosphere contains traces of radon near the ground as a result of seepage from soil and rocks, all of which contain minute quantities of radium. For preparing intense samples a supply of radium is kept in a glass vessel in aqueous solution or in the form of a porous solid from which the radon can readily effuse. At intervals of a few days the accumulated radon is pumped off, purified and compressed into a small tube, which is then sealed and removed.

Radium C rapidly grows into equilibrium with the radon and, since the former is the source of the intensely penetrating gamma rays, the gamma activity is in effect transferred from the radium sample to the tube by this process. The radon can then be used for radiotherapy, radiography or other purposes until its strength decays to too low a value. "Dead" radon tubes are often saved for the extraction of radium D and polonium.

Radon possesses a particularly stable electronic configuration that gives it a chemical inactivity that is characteristic of the noble gas elements. Chemical compounds of radon and fluorine have been synthesized. They are analogous to the xenon fluorides but are less volatile and more stable chemically than the corresponding xenon compounds. Radon fluorides can be distilled under vacuum at a temperature of 250° C.

The radioactivity of radon makes the study of radon compounds by conventional chemical procedures difficult. The physical properties of radon are similar to those expected by extrapolation from the other noble gas elements, helium, neon, argon, krypton, and xenon. It is the most easily condensed and solidified of the group, the boiling point being -62° C and the freezing point -71° C. It dissolves more readily in water than the other noble gases and is very soluble in a number of organic liquids.

RADOWITZ, JOSEPH MARIA VON (1797-1853), the first statesman to attempt the unification of Germany under Prussian military leadership, was born at Blankenburg in the Harz Mountains on Feb. 6, 1797. A Roman Catholic who combined romantic conservatism with a strong will for military efficiency, he entered the Prussian service in 1823, became an artillery expert,

and won the friendship of the crown prince, who in 1840 succeeded to the Prussian throne as Frederick William IV. Since it was then thought that France was likely to attack the territory of the German Confederation, Radowitz began to preach the doctrine of German military union under Prussia, with the emperor of Austria enjoying only a titular supremacy. Yet Radowitz was an isolated figure at the Prussian court and could rely only on personal influence with the king. He occupied only minor posts before the Revolution of 1848.

In 1848 Radowitz sat in the Frankfurt Parliament (see GERMANY: History), where his combination of military knowledge and strict religious views earned him the name of "the Warlike Monk." In April 1849, however, Frederick William refused the imperial crown offered by the liberals of Frankfurt. Radowitz then proposed to win that crown for Prussia by conservative methods, that is, by agreement with the German princes instead of the people. Still without an official position, he became the principal director of Prussian policy and proceeded to organize a union of German states willing to accept Prussia's leadership instead of Austria's. When the Parliament of this union met at Erfurt in March 1850, Radowitz was the chief figure present. He failed, however, to conciliate the other European powers, as he hated the French Republic and was determined to exclude Russia from the Balkans and from the Near East. Furthermore, the Prussian Junkers themselves disliked the policy of adventure into which he was leading them. Radowitz thus could rely only on the hesitant Frederick William, and Prussia was diplomatically isolated.

Against the Erfurt Parliament, Austria revived the old Diet of the Confederation at Frankfurt. Then, in autumn 1850, revolution in Hesse-Kassel (see HESSE) precipitated a crisis between Austria and Prussia. The appointment of Radowitz as Prussian minister of foreign affairs in the last week of September seemed to be the prelude to war; but the other Prussian ministers resisted his policy, the Russian emperor Nicholas I exerted his influence on Austria's side, and Frederick William finally yielded to the pressure for a compromise. Radowitz resigned on Nov. 3 and was sent to London in a vain attempt to secure an alliance with Great Britain in exchange for tariff concessions. By the Austro-Prussian Convention of Olmütz (Nov. 29, 1850) the policy of Radowitz was completely discarded. Thenceforward Radowitz had no influence on Prussian affairs, though he retained the king's personal friendship. He died in Berlin, on Dec. 25, 1853, a disappointed man. He had prematurely anticipated the policy that Bismarck was to carry to success in the Seven Weeks' War of 1866.

RADZIWIŁŁ, a princely family of Lithuanian origin, conspicuous in Polish history. Its earliest known ancestor was Syrpuc, prince of Kiernow in 1280. Fourth in descent from him was Ostik (Krystian), who had a son Radvila, in Polish called Radziwill Ostikowicz (d. 1477). The latter's grandson MIKOLAJ I (d. 1509) was palatine of Wilno and chancellor of Lithuania from 1492.

MIKOLAJ II (1470-1522) succeeded his father Mikolaj I as palatine of Wilno and chancellor. In 1518 he led an embassy to the emperor Maximilian I, who on Feb. 25 made him a prince of the Holy Roman Empire, hoping that he would cease to support the transformation of the Polish-Lithuanian union from a personal into a real one. This Mikolaj had three brothers: JAN MIKOLAJ (d. 1522), castellan of Troki; WOJCIECH (1478-1519), bishop of Wilno; and JERZY (1480-1541), hetman of Lithuania in 1531 and commander in the wars against the Tatars, Muscovy, and the Teutonic Order.

Jerzy's daughter BARBARA (1520-1551) was first married to Stanislaw Gasztold, but after his death (1542) she became the mistress and then, secretly, the wife (1547) of the heir apparent to Poland and Lithuania, Sigismund Augustus. When he came to the throne (1548), his mother, Bona Sforza, and the Polish Senate demanded an annulment of the marriage, but he had Barbara crowned in 1550. The Radziwills became the virtual rulers of Lithuania.

MIKOLAJ the Black (1515-1565), Jan Mikolaj's son, marshal of Lithuania in 1544, chancellor from 1550 and palatine of Wilno from 1551, was an opponent of union with Poland. As Mikolaj I's children left no issue, the emperor Charles V on Dec. 10, 1547, transferred the imperial title of prince to him. Becoming a Cal-

vinist, Mikolaj the Black promoted the Reformation in Lithuania and published the first Polish translation of the Bible (1563).

MIKOLAJ the Red (1512–1584), Barbara's brother, became a Calvinist in 1564 and was the leader of the non-Catholics in Lithuania after the death of Mikolaj the Black, whom he succeeded as palatine of Wilno and chancellor in 1566. Twice appointed hetman of Lithuania (1553 and 1576), he fought well in the wars against Muscovy. His son **KRZYSZTOF MIKOLAJ** (1547–1603), palatine of Wilno from 1584 and hetman of Lithuania from 1589, distinguished himself likewise against the Muscovites and also against the Swedes. Wanting to promote collaboration between the Protestants and the Orthodox Eastern Christians, he objected to the rapprochement of the latter with the Catholics in the Uniate Church.

Mikolaj the Black's sons, who returned to Catholicism and supported King Sigismund III's Counter-Reformation policy, were: **MIKOLAJ KRZYSZTOF** (1549–1616), marshal of Lithuania in 1579, a founder of monasteries, a patron of science, and the author of the vivid *Hierosolymitana peregrinatio* (1601; the narrative of a pilgrimage that he had made to Palestine); **JERZY** (1556–1600), bishop of Wilno and later of Cracow, a cardinal from 1584; **ALBRYCHT** (1558–1592), marshal in 1586; and **STANISLAW the Pious** (1559–99), marshal in 1592, but also a theologian. Stanislaw's son **ALBRYCHT STANISLAW** (1595–1656), chancellor of Lithuania from 1623, was a notable diplomat, published several works on religion, and left valuable memoirs (printed in 1839).

Krzysztof Mikolaj's sons **JANUSZ** (1579–1620) and **KRZYSZTOF** (1585–1640) maintained the Calvinist tradition. Janusz took part in Mikolaj Zebrzydowski's rebellion of 1606–07 against Sigismund III and inaugurated the Radziwills' links with the Hohenzollern dynasty by his marriage (1613) to Elizabeth Sophia, daughter of the elector John George of Brandenburg. Krzysztof, hetman of Lithuania in 1633, campaigned against the Swedes and Muscovites.

Krzysztof's son **JANUSZ** (1612–1655), leader of the Calvinists, ruled Lithuania almost as a sovereign. Palatine of Wilno (1653) and hetman of Lithuania (1654), he put the country under Swedish protection by an act signed at Kiejdany when Charles X Gustavus of Sweden invaded Poland (1655). His first cousin **BOGUSLAW** (1620–1669), son of the elder Janusz and last of the Calvinists, served Sweden and then Brandenburg (1656) against the Poles and made plans with Bohdan Chmielnicki and György Rákóczy II (*q.v.*) for a partition of Poland. Frederick William of Brandenburg made him governor general of Ducal Prussia (1657).

Leadership of the family next passed to the Radziwills of the Nieswiez line, descendants of Mikolaj the Black's son Mikolaj Krzysztof. The latter's grandson **MICHAL KAZIMIERZ** (1625–1680), who married Katarzyna Sobieska, sister of the future king John III (*q.v.*), in 1658 and became palatine of Wilno in 1667 and hetman and vice-chancellor of Lithuania in 1668, was active in the military and diplomatic struggle against the Turks. His son **KAROL STANISLAW** (1669–1719), chancellor of Lithuania from 1698, took the Saxon side in the Northern War (*q.v.*). Karol Stanislaw's son **MICHAL KAZIMIERZ** (1702–62), whose immense wealth and popularity among the nobles greatly helped the Saxon dynasty in the War of the Polish Succession (*q.v.*), became palatine of Wilno and hetman in 1744; his first wife, née Urszula Wisniowiecka (1705–53), was a prolific dramatist and the first in Poland to imitate Molière. Their son **KAROL STANISLAW** (1734–1790), who in 1762 succeeded to the palatinate of Wilno, was an enemy of the house of Czartoryski (*q.v.*) and led a private army to oppose the election of Stanislaw August Poniatowski as king of Poland (Stanislaw II) in 1764. Driven into exile, he reappeared in 1767 at the head of the Russian-sponsored Confederation of Radom, hoping that it would lead to a restoration of the Saxon dynasty. Disillusioned, he next joined the patriotic Confederation of Bar (*q.v.*), but soon had to emigrate again. He recovered his lands in 1776.

After the partitions of Poland **ANTONI HENRYK** (1775–1833), of the fifth generation from the first Michal Kazimierz's brother Dominik Mikolaj, was married in 1796 to Louisa Frederica of Prussia. In the Napoleonic Wars he twice tried to detach the Poles from the French (1806–07 and 1813), with the idea of a

restored Poland under Prussian protection. He was lieutenant governor of Prussian Poznan from 1815 to 1831 and was also a composer of music. His sons **WILHELM** (1797–1870) and **BOGUSLAW** (1809–1873) were members of the Prussian *Herrenhaus*. Boguslaw's son **FERDYNAND** (1834–1926) sat in the German *Reichstag* from 1879 to 1918 and was for many years chairman of the Polish party in it.

In Poland after World War I, Ferdynand's son **JANUSZ KSAWERY** (1880–) led the Conservatives and contributed to their rapprochement with Jozef Pilsudski. His son **STANISLAW** (1914–) was married in 1959 to Caroline Lee Bouvier, sister-in-law of the future U.S. president John F. Kennedy. (E.M. R.)

RAE, JOHN (1813–1893), Scottish Arctic explorer who surveyed and mapped new coast lines of Arctic Canada, was born on Sept. 30, 1813, in the Orkney Islands. He studied medicine at Edinburgh University and was for 10 years resident surgeon at the Hudson's Bay Company's station at Moose Factory. In 1846 he voyaged to Repulse Bay, and the next spring surveyed 700 mi. of new coast line connecting the earlier surveys of J. C. Ross and W. E. Parry. He then joined Sir John Richardson's expedition in search of Sir John Franklin. During 1851 he traveled about 5,300 mi. and explored and mapped 700 mi. of new coast on the south side of Wollaston and Victoria Lands, a feat which gained him the gold medal of the Royal Geographical Society. In 1853 he commanded another expedition which proved King William Land to be an island and elicited the first definite information as to the fate of Franklin. Subsequently he traveled across Iceland, and in Greenland and northern America. He died July 22, 1893, in London. He wrote *A Narrative of an Expedition to the Shores of the Arctic Sea in 1846 and 1847* (1850). (H. G. Kc.)

RAE BARELI, a municipal town and district in the Lucknow division of Uttar Pradesh, India. The town, headquarters of the district, lies on the Sai River, 45 mi. (72 km.) SSE of Lucknow. Pop. (1961) 29,940. It has many architectural features, chief of which is a large brick fort built by Ibrahim Shah in the 15th century. Among other ancient monuments are the palace and tomb of Nawab Jahan Khan, governor under Shah Jahan, and four fine mosques including the Jamma Masjid and the mosque without domes which is a copy of the Ka'ba in Mecca. The town is at the junction of several metalled roads and is an important station on the main railway from Amritsar to Mughal Sarai. It is a trade centre for agricultural products and is well known for its handloom cloth and muslins.

RAE BARELI DISTRICT (area 1,758 sq.mi. [4,553 sq.km.]; pop. [1961] 1,314,949) is slightly undulating and well wooded. The soil is remarkably fertile and the cultivation of a high order, the main crops being rice, pulses, wheat, barley, and millet. The principal rivers are the Ganges (Ganga) and the Sai. (B. Si.)

RAEBURN, SIR HENRY (1756–1823), the leading Scottish portrait painter after Allan Ramsay, was born at Stockbridge,

near Edinburgh, on March 4, 1756. He became a scholar of Heriot's Hospital and in about 1771 was apprenticed to the goldsmith James Gilliland. He is said to have met the seal-engraver David Deuchar in 1773, and the leading Edinburgh portrait painter David Martin in 1775, but for the most part he was self-taught, progressing from miniature painting to full-scale portraiture. A full-length presentation portrait of George Chalmers of 1776 (Dunfermline Town Council) is Raeburn's earliest known portrait, and its faulty drawing and incorrect perspective suggest the artist's lack of formal training. By his marriage to Ann Edgar, a rich widow, early in 1780 he achieved financial se-

BY COURTESY OF THE NATIONAL GALLERIES OF SCOTLAND

SIR HENRY RAEBURN. A SELF- PORTRAIT. IN THE NATIONAL GAL- LERIES OF SCOTLAND

curity and during the next four years considerably improved his artistic skill. In London in 1785 he met Sir Joshua Reynolds, whose works were already familiar to him from Scottish collections and engravings, en route for a prolonged tour of Italy whence he returned to Edinburgh in 1787.

His reappearance was opportune; the rising professional classes of Edinburgh could support a gifted portrait painter and these, with members of the old Highland families, provided him enough sitters. Unlike Ramsay, he never needed to go south in search of patronage. The portrait of "The Archers" (trustees of the late Viscount Novar), of Robert and Ronald Ferguson of Raith, was probably painted soon after his return, and is an ingeniously composed group already showing something of the broad, assured style of his maturity. This concern with elaborate composition was afterward to give place to greater simplicity and directness of presentation. By about 1790 he had painted the outstanding portrait of his wife (Countess Mountbatten collection), a finely characterized work of expressive simplicity, and the double portrait of Sir John and Lady Clerk (Sir Alfred Beit collection), in which the artist experimented with an unusual lighting from behind the sitters' heads (they are in an evening landscape setting) to bring out the character of their faces.

During the years 1790–1800 Raeburn produced some of his most brilliant portraits, such as the dramatic full-length "Sir John Sinclair" (c. 1794–95, Viscount Thurso), a romantic composition of a uniformed Highland laird seen against a mountainous landscape background. This foreshadowed the famous "The MacNab" (c. 1803–13, John Dewar and Sons, Ltd.), in which the tonalities became darker and the lighting even more contrasted. It is significant that no drawings by Raeburn survive; he was essentially a painter rather than a draughtsman. This accounts for the weak drawing of the hands in several of his portraits; he is said to have begun his portraits with the brush, without any preliminary drawing on the canvas. After 1800, he concentrated upon the heads and hands of his sitters, reducing to the absolute minimum all accessories and preferring a dark background to set off his subjects. His technique broadened and he used a vigorous, square brush-stroke with which boldly to model in the features of his sitters. Although this was often extremely effective, as in the "Lord Newton" (1806–11, earl of Rosebery collection) or "Mrs. James Campbell" (c. 1805–12, Colonel Thomas, Glasgow), in his less successful works it became brash and vulgar. Some softening of his brushwork appeared in the last ten years of his career.

In 1810, after the death of John Hoppner, he revisited London with the intention of seeing whether he could establish himself there, but did not pursue this plan. Two years later he was elected president of the Edinburgh Society of Artists, becoming a Royal Academician in 1815. Knighted in 1822, he was appointed His Majesty's limner for Scotland. He died at Edinburgh on July 8, 1823. In many ways Raeburn fulfilled in Scotland the position Reynolds had earlier achieved in London. A popular member of the new cultured Edinburgh society, he rarely associated with fellow artists; he was a man of many interests and a good conversationalist.

RAEDWALD (REDWALD) (d. between 616 and 628), king of the East Angles, was son of Tyttla and grandson of Wuffa. He became a Christian during a visit to the court of his overlord, Aethelberht of Kent, but reverted to paganism on his return, contenting himself with placing an altar to Christ in the same temple as one for the sacrifice to idols. Before Aethelberht's death in 616, Raedwald began to wrest from him the supremacy over the lands south of the Humber and is counted among the Bretwaldas. By his wife's advice he refused to surrender or kill at the request of Aethelfrith of Northumbria the heir to the throne of Deira, Edwin, who had entered his service when in exile. With his support Edwin defeated and killed Aethelfrith at the battle by the River Idle (Nottinghamshire) in 616. Raedwald's son Raegenhere was also

killed. Another son, Eorpwald, succeeded him, not later than 628. See Bede, *Historia Ecclesiastica*, bk. ii, ch. 5, 12, 15; F. M. Stenton, *Anglo-Saxon England*, 2nd ed. (1947). (D. Wx.)

RAEMAEKERS, LOUIS (1869–1956), Dutch cartoonist who gained international fame by his anti-German cartoons during World War I, was born at Roermond on April 6, 1869. He at first painted landscapes and portraits. His first political cartoons appeared in 1907 and he joined the *Amsterdam Telegraaf* in 1909. The sincerity and vigour of his wartime cartoons roused enthusiasm in England, France, and the United States and after 1916 he lived for some years in England to supply the Allied Press more easily. He was also a cartoonist during World War II. He died at Scheveningen near The Hague on July 26, 1956.

RAETIA (so always on inscriptions; in classical manuscripts usually *RHAETIA*) was a Roman province comprising Vorarlberg and Tirol in modern Austria, the eastern cantons of Switzerland, and parts of Bavaria and Württemberg in Germany. The tradition (see Livy, v, 33) that the Raeti were Etruscan can be disregarded, except that there were Etruscan elements in their language: the primitive inhabitants were Illyrian, but Celtic elements predominated early. Roman conquest was carried out in 15 B.C. by Augustus' stepsons Tiberius and Drusus (q.v.), the former operating from Lake of Constance, the latter from the Resia Pass; and the country's subjection was quickly made decisive by road building. Initially there were possibly two legions at Oberhausen near Augsburg, and consequently a senatorial governor. But these troops were withdrawn, probably when advance in Germany was abandoned in A.D. 9, and the province was administered by a Roman knight (called at first *praefectus* and later *procurator*), with a garrison (including native levies) totaling perhaps 9,000 men. With Raetia was coupled Vindelicia (q.v.), and the Vallis Poenina (modern Valais) was for about a century under the Raetian governor's control.

The southern boundary of the territory was the Alpine summit, leaving Tridentum (Trento) in Italy; on the east was Noricum (q.v.); on the west the frontier with Gallia Belgica ran west of Lake of Constance. Under the Flavians the northern frontier, till then on the Danube, was pushed forward to join the new line of fortifications on the Neckar River, and in Hadrian's time the perfected *limes Raeticus* (see *LIMES*) ran in a convex formation of forts to near Castra Regina (Regensburg). Under Marcus Aurelius, who was faced with new barbarian threats, a legion (*legio III Italica*) was stationed at Regensburg, and its senatorial commander became governor of the province. The 3rd-century invasions pressed heavily on Raetia. As early as 234 the Alamanni were attacking the *limes*; and its western sector was withdrawn south of Lake of Constance about 260 and possibly never restored to its old line, though Castra Regina was maintained. For a generation after this there was almost constant fighting in northern Raetia. In the 4th century the province (divided into two by Diocletian) was firmly held, but by 450 the whole country down to the Alps had passed into barbarian possession.

The Roman roads of Raetia illustrate its importance for communications between Italy and the Danube and between Gaul and the Balkans. In 47 Claudius as emperor completed the Via Claudia Augusta along the route of his father's conquest, up the Adige Valley and across the Resia to Augsburg and the Danube; and under Septimius Severus a road was carried across the Brenner Pass. Another great highway from Brigantium (Bregenz) to Curia Raetorum (Chur) was continued over the Splügen Pass to Mediolanum (Milan), though its date of construction is unknown. For its culture Raetia looked more to Gaul and the Rhineland than to the other Danubian provinces. The northern area (including that between Danube and *limes*) was rich in timber, pitch, and iron; but the economic value of the province as a whole was small, and its romanization went much less deep than that of the neighbouring province of Noricum.

BIBLIOGRAPHY.—J. Whatmough, *The Foundations of Roman Italy*, ch. 7 (1937); F. Stäbelin, *Die Schweiz in römischer Zeit*, 3rd ed. (1948); W. W. Hyde, *Roman Alpine Routes* (1935). (G. E. F. C.)

RAETO-ROMANCE DIALECTS are spoken by about 450,000 persons in the Alpine regions of southeastern Switzer-

land and northern Italy, including the Friuli region. They do not cover a contiguous area; they do not now and never did belong to a single cultural, administrative or linguistic unit; and they are not written in any single standard language. They are also not founded upon the same pre-Latin linguistic substratum, nor do they have the same linguistic superstratum. Apart from being all Romance, that is, Neo-Latin dialects, they owe their being classified together under one name not so much to their similarities, which merely suffice to set them off from all other Romance dialects, as to their geographic location. The term Raeto-Romance (RR) has, therefore, been contested on various grounds; for example: it had little to do with the Latin province called Raetia, which covered a larger surface, though not so dispersed; it had even less to do with a pre-Roman population called Raeti, whose dialect, imperfectly known, forms the substratum of only a small part of RR; all dialects concerned should be called Ladin in order to avoid Raetic connotations, and RR should be restricted to the dialects of Switzerland; the term RR should be abandoned altogether because all dialects concerned are really Italian: the western of the Lombard group and the eastern of the Venetian group. All these terminological disagreements bedevil the linguistic literature, which must, therefore, be used with proper caution. National animosities and disputes, many still alive, have penetrated (linguistic) research, particularly regarding the districts of northeastern Italy: the Alto Adige (the former Austrian South Tirol) and Friuli.

The RR dialects are spoken in three major areas: (1) In Friuli, the region between the Alps and the head of the Adriatic sea, with the capital at Udine. This idiom is called Friulian. It accounts for over 90% of the total number of speakers of RR. (2) In some valleys of the Alto Adige region, east and west of the city of Bolzano, and in some parts of the Dolomites. This idiom may be called Ladin. (3) In parts of the Swiss canton Grisons (Graubünden), in particular in the valleys of the two confluent of the Rhine (the Vorderrhein and the Hinterrhein), and of the Inn (the Engadine, Upper and Lower), approximately as far as the Austrian border. These dialects are called Romansh (or, in the native tongue, Grishun) and may be subdivided into Surselvan (Vorderrhein), Sutselvan (Hinterrhein) and Engadinian (Inn).

There is no doubt that at one time the area of RR was much larger. But owing to the absence of documentation it is difficult to learn when a given district changed to another type of speech, Italian or German. In many areas, however, the switch is relatively recent. For example, the Inn valley between Finstermünz, Switz., and Imst, Aus., from the Swiss border halfway to Innsbruck, spoke RR until the 16th century; there were Romance minorities in the Vintschgau as late as the 18th century and in some villages into the 19th; Innsbruck did not become wholly German-speaking until the 13th century, and Vorarlberg, Aus., even later, especially the Montafon (valley of the Ill river); the Rhine valley past Liechtenstein, and the Wallensee area west of it, were Romance until the 11th century; Chur, the capital of the Grisons, was prevalently of Romance speech until the beginning of the 15th century.

The retreat of RR before Italian and German continues under the impact of the national languages which have greater prestige and currency. Friulian will probably cede to standard Italian, as will all dialects of the state of Italy; whether Ladin will be replaced by German or Italian is not certain: it is spoken within the Italian state, but its nearest and most influential neighbouring language is German (Austrian-Bavarian) of Bolzano-Merano. Romansh of Switzerland is in a slightly more favourable situation; it is spoken in a country where local dialects, both Germanic (Alamannic) and Romance, are not considered socially inferior but cultivated and cherished. Romansh has also been best described of all the RR dialects, has been codified in dictionaries and grammars, has a literature (including a translation of the New Testament of 1560) and has in fact been the fourth official language of Switzerland since 1938.

Ethnically the area of RR has been mixed and unstable from prehistoric times. "Because of its passes it has always served as the crossroads between east and west, and north and south; and

because of its inaccessible valleys and heights it has likewise served as a refuge for populations driven in war from more hospitable surrounding regions. Preceding its Latinization it was most likely of Celtic and Raetic speech in its western parts, of Italic (Venetic) speech in its eastern parts. But it is impossible to draw sure boundaries for these linguistic substrata or to give dates for their Latinization. The political conquest of the district of Friulian, a part of Gallia Cisalpina, occurred around 220 B.C., but the Alpine area of Ladin and Romansh was not conquered until 15 B.C., when it became in part the province of Raetia.

All these beautiful but poor mountainous tracts, Raetia, Noricum, Vindelicia, seem to have interested the Romans mainly for logistic reasons, in order to keep open communications with Gallia Transalpina and other northern and western possessions. Hence these regions were neither as intensively nor as extensively Romanized in culture and speech as other parts of the Roman empire which are now Romance-speaking. Furthermore, the Alpine provinces were the first to fall before the onslaught of the Germanic tribes which invaded Roman soil in the 5th century: the Alamanni pushed south across Switzerland about the end of the 5th century; the Bajuvarii crossed the Brenner pass, reaching the upper Isarco valley about 600 and the Bolzano-Merano district around 765. Friuli was the territory through which the invading Ostrogoths and Visigoths moved into Italy; it became eventually a Langobardic possession, but it was no more Germanized by these German tribes than was the rest of Italy. If the Germans had been better organized and if they had pursued a common goal, such as a Germanic state on the soil of the Roman empire, the entire RR area, if not, indeed, large portions of Italy, might have become Germanic in speech. Or if the speakers of the different RR districts had formed a coherent political whole, the various RR idioms might eventually have brought forth a separate standard Romance language. In view of the extremely checkered history of the area throughout the middle ages and into the modern era, the linguistic situation has become difficult to analyze.

The few linguistic traits common to all RR languages are archaisms rather than common innovations. This testifies to a lack of communication among them and the absence of a common culture. The greatest amount of agreement is to be found in the vocabularies of the various dialects; but this is not very significant, since they are all of Latin origin. In phonology the retention of Latin final -s over large areas is important both phonemically and morphemically. In the latter respect it causes plural formations with -s, thus connecting RR with the western, Gallo-Romance languages. Otherwise the retention of *pl-*, *kl-* (*cl-*) and *bl-* (rather than palatalization, as prevails in Italian and Rumanian), the palatalization of *ka-* (*ca-*) and *ga-*, and the diphthongization of vowels in free (that is, syllable-final) position are widespread but far from ubiquitous. Of all the Romance idioms, the RR languages have been least studied because of the scarcity of records of the medieval and even modern period and the absence of any standard literary language or languages. Outside of Switzerland all RR speech is considered mere patois. The description of contemporary speech awaits modern scientific treatment; but it will have to be undertaken soon, lest RR go the way of other now extinct Romance speech forms.

RAFF, (JOSEPH) JOACHIM (1822-1882), Swiss composer who wrote in the style of Mendelssohn and Liszt, wrote over 300 works including 11 symphonies, chamber music, and choral works, and many piano pieces. He was long known for his "Cavatina" for the violin. Born on May 27, 1822, at Lachen, Lake of Zürich, Raff became a schoolteacher at Rapperswil in 1840 and taught himself the piano, violin, and composition. In 1844 he went to Zürich where he devoted himself to composition and teaching.

In 1848 the pianist Hans von Bülow played Raff's *Concertstück* at Stuttgart. In 1850 Raff went to Weimar where his opera *König Alfred* was given the following year. Between 1856 and 1877 he was a piano teacher at Wiesbaden, producing during this period seven symphonies and his comic opera *Dame Kobold*. In 1877 he was appointed director of the Konservatorium at Frankfurt am Main and died there on the night of June 24–25, 1882.

See Helene Raff, *Joachim Raff* (1925).

RAFFI (pseudonym of HAKOB MELIQ-HAKOBIAN) (1835–1888), the most celebrated Armenian novelist, was born in Phayajuk, in Iranian Azerbaijan, the eldest son of a merchant. After his father's bankruptcy in 1868, he worked as a schoolmaster and a journalist, collaborating with the Russian-Armenian paper *Mshak* from 1872 to 1884. He died in Tiflis, where he is buried. His principal novels are *Jaleddin* (1878), *The Fool* (1880; Eng. trans. 1950), *David Bek* (1880), *The Golden Cockerel* (1882), *Sparks* (1883–1890), and *Samuel* (1885). He wrote also a number of short stories and historical articles.

An ardent nationalist, he was preoccupied with the lot of his fellow Armenians in Persia and Turkey, and his interest in history was that of a writer of the Romantic school. He had a fertile imagination and narrative skill, but the psychology of his characters tends to be shallow, and the construction and style of his work uneven. (C. J. F. D.)

RAFFIA, a fibrous product obtained from the palm *Raphia pedunculata* of Madagascar. It is prepared from the leaves of the palm, which are cut before they begin to curl. The underpart is removed in strips and dried, after which the strips can be split easily from end to end in any desired width.

Raffia is used in connection with the tongue grafting method of tree or shrub propagation. A tongue cut on the face of the scion (cion) is fitted into a matching notch on the parent stock, and scion and stock are securely bound together with raffia.

Raffia is also widely used in basketry, particularly in the sewing of coiled reed or plaited rush baskets. It may also be woven in the conventional manner by passing it under and over warp strings on a loom.

Raffia can be satisfactorily dyed with vegetable colourings, such as those derived from barks, leaves, berries, and flower petals.

(E. L. Y.)

RAFFLES, SIR THOMAS STAMFORD (1781–1826), British colonial governor and founder of Singapore, was born on board his father's merchantman, off Port Morant, Jamaica, on July 6, 1781. Educated at the Mansion House Boarding School, Hammersmith, London, he entered the service of the East India Company in 1795, was appointed a permanent clerk in 1800, and, five years later, was posted as assistant secretary to the presidency government of Prince of Wales Island (Penang, Malaya).

He arrived there on Sept. 19, 1805, and became secretary to the government 18 months later. His heavy official duties soon undermined his health, but during a period of recuperative leave at Malacca between August and October 1808, he prepared a long report which argued so convincingly against the company's proposal to abandon the settlement that orders for the evacuation were countermanded.

The report on Malacca brought Raffles under the notice of the Bengal authorities, and in June 1810 he visited Calcutta, where he was received cordially by the governor-general, Lord Minto. In October, Britain being at war with France, which had occupied the Netherlands, he was appointed agent with the Malay States to prepare the way for the British invasion of Java.

The British expeditionary force under Sir Samuel Auchmuty, and accompanied by Lord Minto, consisted of about 11,000 troops, transported in 57 ships. On Raffles' recommendation the fleet sailed by the direct passage through the Karimata Strait and arrived safely off Java in July 1811. Batavia (Jakarta) was occupied without opposition, and the combined Dutch-French forces under Jan Willem Janssens, the governor-general, were defeated at Meester Cornelis on Aug. 26.

Lord Minto's instructions were to withdraw the British forces from Java after its reduction, but, as he felt repugnance at leaving unarmed Dutch colonists at the mercy of the Indonesians, he es-

tablished a provisional British administration with Raffles as lieutenant governor. Thereafter, until his departure in March 1816, Raffles' energies were devoted to the task of reforming the Dutch colonial system. This system, which aimed at the collection of tropical produce by means of forced deliveries and contingents, was closely geared to the Indonesian economic and social organization; it appeared to Raffles, however, to be based upon forced labour and compulsion, so he attempted to substitute in its place a land rent system, founded on principles of free cultivation. The new system was designed not only to supply the treasury with much needed funds, but, by establishing a money economy, to throw open Java to British manufacturers. In both objectives it failed during the short-lived British administration, but the system was important in giving direction for future colonial reform under the Dutch, who returned to Indonesia in 1816.

Raffles arrived back in England in July 1816 and was elected a fellow of the Royal Society in March 1817. His book, *The History of Java*, was published in May 1817, and he was knighted shortly afterward. In November he sailed to take up his appointment as lieutenant governor of Ft. Marlborough (Bengkulu, Sumatra).

During his Sumatran administration, Raffles attempted to reform the system of forced pepper cultivation in the company's districts, and at the same time made a number of unsuccessful efforts to prevent the restoration of the Dutch to Padang and elsewhere in the island. In the belief that British influence should be extended in southeast Asia, he sailed for Bengal in September 1818 in order to draw the attention of the governor-general, Lord Hastings, to the aggressive nature of Dutch policy in the region. He quickly gained Hastings' confidence and was instructed to establish a settlement at the southern entrance to the Malacca Strait. There, on Feb. 6, 1819, he raised the British flag on the island of Singapore (q.v.). After a brief period of absence at Benkoelen, he returned to Singapore in October 1822, when he organized the various branches of the administration. He left the East for England in April 1824, secure in the knowledge that Singapore was a flourishing free-trade port.

Raffles died at his country house at Highwood, near Barnet, on July 5, 1826. Before his death he helped to found the London Zoological Society, of which he was the first president.

Wurtzburg, *Raffles of the Eastern Isles* (1954); J. Bastin, *The Native Policies of Sir Stamford Raffles in Java and Sumatra* (1957). (J. S. Bx.)

RAFFLESIA, a genus of six species of plants native to the forested mountains of Malaya. They are of interest for their bizarre flowers, the largest known in the world. The plants, having no green parts, are parasitic on species of *Tetrastigma*, mammoth woody vines belonging to the grape family. The sticky seeds of *Rafflesia* germinate in the rough bark of the basal stems of *Tetrastigma*, which lie on the ground. Each seed produces threadlike strands that penetrate the stem and absorb nourishment. The new plant produces a small flower bud soon after the seed germinates, but forms no stem, leaves, or true roots. About nine months later the fully opened flower is 15–28 in. across (some reports give 3 ft.) and weighs 12–24 lb.; it remains open for five to seven days. Each flower, either male or female, has five limp, fleshy, petal-like segments, coloured reddish- or purplish-brown and sometimes mottled. The sex organs are inside a partially covered central cup, coloured fiery red. The flowers emit a fetid odour of rotting meat. Pollination is believed to be effected by carrion-feeding flies attracted by the odour, and seed dissemination is thought to be accomplished by fruit-eating rodents.

(G. H. M. L.)

RAFINESQUE, CONSTANTINE SAMUEL (1783–1840), a naturalist and early theorizer about the evolution of species, was born of French-German parents at Galata (Constantinople) on Oct. 22, 1783. He lived in Marseilles and after 1792 in Italy, studying in Leghorn, Genoa, and Padua. In 1802 he went with his brother to the United States. He worked in Philadelphia and Germantown, Pa., visited Pres. Thomas Jefferson at Washington, and made many trips in search of natural history specimens.

In 1805 he returned to Europe, spending the next ten years in Palermo, Sicily. In 1815 he returned to the United States, where he taught and made botanical collections. In 1819 he became professor of botany, materia medica, and modern languages at the Transylvania University, Lexington, Ky., where he founded a botanical garden in 1825. In 1826 he moved to Philadelphia where he lectured at the Franklin Institute. He died in poverty in Philadelphia on Sept. 18, 1840.

Rafinesque was a controversial figure in the history of U.S. botany. He was severely criticized by such an authority as Asa Gray (*q.v.*) for careless work and his passion for establishing new genera and species. On the other hand, he was lauded as a genius who had a definite idea about the theory of evolution long before Charles Darwin.

His publications numbered more than 950; the most important among his botanical works are: *Autikon botanikon* (1815–40, facs. ed., 1942); *Florula ludoviciana* (1817); *Medical Flora*, 2 vol. (1828–30); *New Flora and Botany of North America*, 4 pt. (1836–38); *Flora telluriana*, 4 vol. (1837–38); *American Manual of the Mulberry Trees* (1839) and *Sylva telluriana* (1838, facs. ed., 1942). He also wrote *A Life of Travels and Researches* (1836, facs. ed. 1943).

See T. J. Fitzpatrick, *Rafinesque, a Sketch of his Life with Bibliography* (1911) and F. W. Pennell, *The Life and Work of Rafinesque* (1942). (V. C. As.)

RAGES: see RAY.

RAGLAN, FITZROY JAMES HENRY SOMERSET, 1ST BARON (1788–1855), British field marshal, commander in chief of British troops during the Crimean War, was born at Badminton, Gloucestershire, on Sept. 30, 1788, the youngest son of Henry, 5th duke of Beaufort. He was first commissioned in 1804 and at the outbreak of the Peninsular War in 1808 went to Portugal as aide-de-camp to Sir Arthur Wellesley (afterward 1st duke of Wellington) with whom he remained closely associated for much of his military service. Somerset was wounded at Bussaco (1810) and distinguished himself at the storming of Badajoz (1812); in the Waterloo campaign (1815) he received a wound which necessitated the amputation of his right arm. He had been military secretary to Wellington from 1810 to 1814 and served him again in this capacity when the duke became master general of the ordnance in 1818, retaining the position in 1827 when Wellington became commander in chief. His tact, urbanity, punctuality, and accuracy made him invaluable to the duke. When Wellington died in September 1852, Somerset became master general of the ordnance and in October was raised to the peerage as Baron Raglan of Raglan. In 1854 he was appointed commander in chief of the British expeditionary force sent to Turkey and to the Crimea.

In his conduct of the campaign in the Crimea, which has always been much criticized, he was severely hampered by the neglect of successive British governments to equip the army for long and arduous military service, and by the necessity of cooperating with intransigent allied commanders. It was against his judgment that the British, French, and Turkish forces were sent to the Crimea in September 1854 to attack the strong naval fortress of Sevastopol. After the victory at the Alma (Sept. 20) he was opposed to the march around Sevastopol to besiege the city from the south, favouring instead an immediate assault from the north, but for the sake of allied unity and cooperation he agreed to the views of the French military commanders on this and later occasions.

After the battles of Balaklava (Oct. 25, 1854) and Inkerman (Nov. 5), in the second of which Raglan showed great personal courage and leadership, he was made a field marshal. His troops had then to endure a fierce winter without proper clothing, supplies, or accommodation, all of which it was the government's responsibility to supply. Although Raglan was made the target of much ill-informed and partisan criticism, he refused to justify himself at the expense of his staff or the government in England. With the advent of better weather early in 1855, the siege of Sevastopol was more vigorously pressed, but a combined assault on June 18 by the allied armies was repulsed with heavy loss. Raglan was then gravely ill and this failure so aggravated his weakness that

he died in the camp before Sevastopol on June 28, 1855, "the victim," wrote Gen. Sir Evelyn Wood, "of England's unreadiness for war." He was buried on July 26, 1855, at Badminton.

See C. Hibbert, *The Destruction of Lord Raglan* (1961).

(E. W. SH.)

RAGNAR LODBROK (fl. 9th century A.D.), a Viking hero, appears first as a purely genealogical figure. In the English *Annals of St. Neots* (early 12th century) he is the father of Inwaer (Ivar the Boneless) and Hubba (Ubbe), Scandinavian brothers who attacked England in the 9th century. Slightly earlier, the German historian Adam of Bremen (*c.* 1075) made him father of Inwaer, and William of Jumièges (*Gesta Normannorum ducum*, *c.* 1070) thought him father of a Viking, Berno (Bjorn), who appears in continental annals in 855 and 858. Modern authorities have added to Ragnar's sons Sigefridus, who figures in continental annals from 873 onward, and some have attempted to give Ragnar further historicity by identifying him with Reginherus, a Viking who invaded France in 845.

In history, therefore, Ragnar is little more than a genealogical figure. Later sources, however, surround his name with legend to a remarkable degree. So, in the *Gesta Danorum* (*c.* 1185) of Saxo Grammaticus (*q.v.*), he is a 9th-century Danish king, whose wars and expeditions are detailed at great length and include a clash with Charlemagne. Ragnar was ultimately captured by the Anglo-Saxon king Aella of Northumbria and cast into a snake pit to perish. His sons later avenged him. This story also appears in the Icelandic version of Ragnar's legendary history, given in the very late works *Ragnarssaga* and *Tháttr af Ragnarssonum*. These works retail a version of the legend generally agreeing with that upon which the violent 12th-century poem *Krákumál* is based. In this version Ragnar links history with legend by marrying a daughter of Sigurd (Siegfried) and Brynhild (Brunhild).

Ragnar may be the Lodbrok mentioned in a runic inscription found in the Orkneys, apparently claiming that a how (barrow) was built to commemorate him.

BIBLIOGRAPHY.—A. Mawer, "Ragnar Lothbrók and His Sons," and A. H. Smith, "The Sons of Ragnar Lothbrok," *Saga Book of the Viking Society*, vol. vi (1908–09) and xi, part ii (1935); J. de Vries, "Die historischen Grundlagen der Ragnarssaga Lothbrókar," *Arkiv för nordisk Filologi*, vol. xxxix (1923); *The Saga of the Volsungs: the Saga of Ragnar Lodbrok together with The Lay of Kraka*, Eng. trans. by M. Schlauch (1930). (A. L. C.)

RAGNARÖK, in Scandinavian mythology, the name for the end of the world of gods and men. The word means literally "Doom of Gods." A later form, *Ragnarökkr*, meaning "Dusk [Twilight] of Gods," was adopted by Richard Wagner for his opera *Götterdämmerung*.

The Ragnarök is fully described only in the Icelandic poem *Völuspá* ("Sibyl's Prophecy"), probably of the late 10th century (see ICELANDIC LITERATURE: *Mythological Lays*); and in the 13th-century *Prose Edda* (see EDDA) of Snorri Sturluson (d. 1241), which largely follows the *Völuspá*. It will be preceded by cruel winters and moral chaos. Giants and demons approaching from all points of the compass will attack the gods, who will meet them and face death like heroes. The sun will be darkened, the stars vanish, and the earth sink into the sea. Afterward earth will rise again; the innocent Baldr (see BALDER) will return, and the hosts of the just will live in a hall roofed with gold. (See also GERMANIC MYTHOLOGY AND HEROIC LEGENDS.)

Disjointed allusions to the Ragnarök, found in many other sources, show that conceptions of it varied. According to one poem two human beings, Lif and Lífthrasir ("Life" and "Life-holding"), will survive it and repopulate the earth. It is widely held that Scandinavian conceptions of the Ragnarök were influenced by Christian and Oriental conceptions of the Day of Doom.

(G. T.-P.)

RAGUSA, a town and capital of Ragusa Province, Sicily, stands in the Iblei (Hybla) Hills above the gorge of the Irminio River in the southeastern tip of the island, 69 mi. (112 km.) WSW of Syracuse by rail and 54 mi. (87 km.) by road. Pop. (1961) 57,248 (commune). The upper (modern) town is separated from the lower town (on the site of the ancient Hybla Heraea) by a declivity. After an earthquake in 1693 had destroyed

most of the old town a new town was built to the west, the two communes created after the earthquake being united in 1926. Handsome Baroque buildings include the cathedral (1706–60) and the Basilica of S. Giorgio (1738–75). Some 15th-century fragments survive in Sta. Maria delle Scale and the portal of S. Giorgio Vecchio. Nearby are petroleum wells and asphalt mines, and cement is manufactured. The town, formerly an agricultural centre, has asphalt products and a polythene plant.

RAGUSA PROVINCE comprises the western half of the southeast-ern tip of Sicily. Area 623 sq.mi. (1,614 sq.km.). Pop. (1961) 252,769. The province, formed in 1927 and drained by the Irmínio and Acate (Dirillo) rivers, is mountainous in the north, including part of the Iblei Range. Cattle and sheep are raised, and cotton, wheat, and carob beans are grown. The province is the main asphalt-mining area of Italy. (Cr. M.)

RAGUSA, Yugoslavia: see DUBROVNIK.

RAGWEED, any North American plant of the genus *Ambrosia* (family Compositae). The ragweeds are chiefly coarse annuals, with rough hairy stems, mostly lobed or divided leaves, and inconspicuous greenish flowers borne in small heads, the male in terminal spikes and the female in the upper axils of the leaves. The common ragweed (*A. artemisiifolia*), called also Roman wormwood, hogweed, and bitterweed, found across the continent, grows from one to seven feet high, with thin, alternate or opposite, much-divided leaves. The great ragweed (*A. trifida*), called also bitterweed and horse cane, native from Quebec to British Columbia and southward to Florida, Arkansas, and California, grows from 3 to 17 ft. tall, with opposite, entire, or palmately three- to five-lobed leaves. Both the foregoing are annuals and often become pernicious weeds; their pollen, which is shed in great abundance in late summer, is a prolific source of hay fever (*q.v.*). Since these species are annuals, their eradication is easy if they are mowed well before they shed their copious seed. The western ragweed (*A. psilostachya*), found from Illinois to Alberta and southward to California, Texas, and Mexico, is similar to the common ragweed, but is a shorter plant, perennial, and with thicker leaves. All the ragweeds, annual and perennial, can be killed with 2,4-D.

In England, the tansy ragwort *Senecio jacobaea* (see *SENECIO*) is sometimes called ragweed. (N. Tr.)

RAHAB, the name of two Old Testament figures.

1. Rahab was a Jericho woman who sheltered the spies sent by Joshua (Josh. 2), concealed them under flax on the roof, and assisted them to escape by a rope from a window of her house on the town wall. By this act of friendship she secured the safety of her household when the Israelites took Jericho; by arrangement a scarlet cord was to be hung from a window for identification. Thus, she and her family were saved and became converts to the Hebrew religion. The Hebrew text describes her as a harlot (*zonah*), and she is so regarded in talmudic literature. Later Jewish commentators, however, prefer to associate *zonah* with an alternative root to procure the meaning "one who sells food." Rahab's beauty was proverbial, and from her profession she was reputed to be well informed on public affairs. After her conversion, according to tradition, she married Joshua and became the ancestress of Jeremiah, Huldah, and Ezekiel among other prophets.

2. Rahab was the name of the sea monster inhabiting the primeval ocean (Ps. 89:10; Job 9:13; 26:12; Is. 51:9; comparable with Tiamat in Assyrian-Babylonian mythology); hence, in a figurative sense, a designation for Egypt (Ps. 87:4; Is. 30:7).

RAHWAY, a city of Union County, New Jersey, U.S., is 20 mi. SW of New York City. Industrial establishments in Rahway produce drugs, chemicals, varnish, machinery, auto accessories, vacuum cleaners, office equipment, books, food products, rubber goods, and textile goods. The city is also a residential centre. For comparative population figures see table in NEW JERSEY: Population.

The city was settled in the 1680s. During the American Revolution (when it was called Spanktown) it was temporarily an army supply base for General Washington's army and a skirmish was fought there in January 1777. It became a township in 1804 (called Rahway after a local Indian Chief named "Rahwack") and a city in 1858. (W. L. CA.)

RAICHUR, a town and district in the Gulbarga division of Mysore, India. The town, headquarters of the district, lies at the junction of Southern and Central railways, 334 mi. (538 km.) N of Bangalore. Pop. (1961) 63,329. It has a fort, an ancient palace, and a college affiliated to Karnatak University. The town is a commercial centre and has oil mills, cotton ginning and pressing, and soap factories.

RAICHUR DISTRICT has an area of 5,491 sq.mi. (14,222 sq.km.). Pop. (1961) 1,100,895. It is drained by the Krishna and Tungabhadra rivers and is a *doab* (interfluvium). The plateau is broken occasionally, and there are ranges of isolated hills (northwest). Mineral resources comprise gold, iron ore, limestone, and manganese. Cotton is grown on the black retentive soil. There are cotton-ginning and pressing factories, oil mills, and sugar manufacturing at Munirabad. (G. K. GH.)

RAIGARH, a town and district in the Bilaspur division of Madhya Pradesh, India. The town, headquarters of the district, lies on the South Eastern Railway, 363 mi. (584 km.) WSW of Calcutta. Pop. (1961) 36,933. It has an old fort and a jute mill. There is a considerable handloom industry, and fine tussah (tasar) silk and glass bangles are made. The arts and science college and the government polytechnic are affiliated to Saugar University.

RAIGARH DISTRICT has an area of 15,064 sq.mi. (39,016 sq.km.) and a population (1961) of 1,041,226. The district was formed from the old princely states of Raigarh, Sarangarh, and Jashpur. The Chauwadhari Range runs east-west through the centre of the district, south of which lies the Raigarh Plain drained by the Mand and Kelo rivers. The ruling family of Raigarh were the Rajgond who belonged to Wairagarh in Chanda District (Maharashtra). Rice is the main crop followed by pulses and oilseeds. The forests yield sal, a valuable timber. Most of the inhabitants are tribespeople like the Gonds and Rawats who speak the Chhattisgarhi dialect of Hindi. (D. G. NA.)

RAIKES, ROBERT (1736–1811), English philanthropist and pioneer of the Sunday school movement, was born at Gloucester on Sept. 4, 1736. His philanthropic work started with the prisoners in the local jail. Later, the lawless behaviour of Gloucester children on Sundays led him to experiment with a Sunday school in Sooty Alley, where he engaged a number of paid women teachers to give instruction in reading and the church catechism. The experiment was so successful that in his newspaper, the *Gloucester Journal* (Nov. 3, 1783), he was able to record that the district had become "quite a heaven upon Sundays, compared with what it used to be." The Sunday school movement spread to all parts of the country with great rapidity. In 1785, the Sunday School Society was formed, and four years later Sunday schools were established in Wales. The Sunday School Union (1803) was a direct result of Raikes's work. He died at Gloucester on April 5, 1811.

BIBLIOGRAPHY.—A. Gregory, *Robert Raikes* (1877); J. H. Harris, *Robert Raikes, the Man and his Work* (1899); G. Kendall, *Robert Raikes* (1939). (S. J. C.)

RAIL, the common name for marsh birds comprising the family Rallidae, of which there are more than 130 species recognized, worldwide in distribution except in high latitudes. They are somewhat chicken-shaped, with short rounded wings and large feet with long toes. Rails are secretive in habit and infrequently seen; their loud, harsh calls, however, give away their presence in dense vegetation. Many are excellent game birds; when flushed, they take to wing reluctantly, flying a short distance and then dropping to the ground.

In the United States the king rail (*Rallus elegans*), a reddish-brown bird the size of a small chicken; clapper rail (*R. longirostris*), a gray form; and the Virginia rail (*R. limicola*), reddish brown and less than one-half as big, are hunted as game, as is the Carolina rail, or sora (*Porzana carolina*). The little yellow rail (*Coturnicops noveboracensis*) and the six-inch-long black rail (*Laterallus jamaicensis*) are too scarce to be of interest to the hunter.

The land rail, or corn crake (*Crex crex*), is found throughout Europe and western Asia and is a summer visitor to England. Brownish above and yellowish white below, it is inconspicuous

except in flight, when it is recognized by its chestnut wings, barred flank, and dangling legs. It nests on the ground and forages for food, chiefly insects, in long grasses. Eight to ten eggs are laid, of a cream colour blotched with red-brown. The young hatchlings are covered with black down. Less abundant but more widely distributed (extending to northern Africa) is the water rail (*Rallus aquaticus*). This is a slender bird of much the same habits as the corn crane. It is distinguished by darker plumage and a long, reddish bill.

HUGH M. HALLIDAY FROM NATIONAL AUDUBON SOCIETY

VIRGINIA RAIL (*RALLUS LIMICOLA*)

The Rallidae includes also coots and gallinules (*qq.v.*) and, among a few flightless sorts, *Notornis*, a genus presumed to be extinct till small groups of *N. hochstetteri* were found in 1948 along some alpine lakes of New Zealand. Several rails live on tiny almost barren oceanic islands. (Ht. FN.)

RAILWAY, a mode of land transportation the roadway of which consists of one or more tracks, each having two parallel steel rails. Over these rails move freight and passenger carrying vehicles, or cars, with flanged wheels. The cars are usually pulled or pushed by a locomotive, although they may be self-propelled.

TABLE I.—U.S.-British Railway Terms

United States	Britain
Baggage car	Luggage van
Boxcar	Goods van or box van
Classification yard	Marshaling yard
Caboose	Brake van
Crosstie or tie	Sleeper
Diaphragm (car)	Corridor connection
Dining car	Restaurant car
Engineer; engineman	Engine driver
Freight car	Goods wagon
Grade crossing	Level crossing
Gondola car	Open wagon
Interlocking plant	Signal box
Journal box	Axle box
Joint bars (rail)	Fishplates
Passenger car	Passenger carriage
Self-propelled car	Rail car
Self-propelled-car train	Train set
Signal tower	Signal cabin
Switching (of cars)	Shunting
Switcher (locomotive)	Shunting engine
Switch or turnout	Points
Tie plate	Baseplate
Truck, swivel car	Bogie

The development of railways is one of the great landmarks in the progress of human civilization. Coming early in the 19th century, railways provided an element that was essential to full realization of the promise of the surging industrial revolution—namely, a reliable, low-cost, high-volume system of land transportation.

It is the principle of flanged steel wheels rolling on steel rails that gives the railway its pre-eminence for heavy-duty transportation. The flanges guide the wheels of locomotives and cars, causing them to follow the line of the rails, and the rolling friction of the wheels on the rails is extremely low! In fact, if a 40-ton railway freight car of the type common in the U.S. were set rolling on level track at 60 m.p.h., it would travel five miles or more before coming to a stop. In contrast, a highway truck of similar weight set free on level road at the same speed would roll only about one mile.

Because of this self-guiding characteristic and the low rolling friction, a locomotive of relatively modest horsepower can pull a long train of cars. This, basically, is the reason for the economy of railway transportation, an economy that is clearly evident in terms of manpower and fuel consumption. In 1952, for example, all other forms of transport in the United States used 11 times as much fuel as did the railways—yet the latter produced more than half the total gross ton-miles of transportation. In 1955, U.S. railways produced five times as much transportation per employee as did the intercity truck lines, despite the fact that the railways build and maintain their own roadways, which the highway carriers do not.

This discussion is divided into the following sections:

I. Historical Development

A. Railways in the United States

1. The Westward Movement
2. Land Grants
3. Railway Regulation
4. Labour Relations
5. U.S. Developments to World War II
6. U.S. Railways in War

B. Railway Growth in Canada

2. New Forms of Signaling
3. Automatic Train Controls
4. Automation of Train Operations

VIII. Classification (Marshaling) Yards

IX. Co-operation Among Railways

1. North American Organizations
2. European Organizations

X. Conclusion

Information on the economic aspects of railway operation may be found in the article *INTERSTATE COMMERCE*, while a general survey, from a historical viewpoint, of all forms of transport is presented in the article *TRANSPORTATION*. Forms of urban and interurban rail transport are described in *ELECTRIC TRACTION* and *SUBWAY (UNDERGROUND RAILWAY)*.

I. HISTORICAL DEVELOPMENT

The railway as we know it originated in England, but the use of wheeled vehicles on rail lines came many years before the advent of mechanical traction. There is a reference to a railway in Europe as early as 1550. Before the end of the 16th century, mining railways were introduced in Britain, particularly in the northeast coal-mining area. In the 18th century horse-drawn railways of this kind were to be found not only in England but in Wales and Scotland. Their application was increased with the introduction of cast iron for wheels and for the plateways over which the wagons ran. The earliest atmospheric steam engines, however, were too bulky and heavy for traction purposes.

In 1797 Richard Trevithick made three models, one of which may have represented a proposal for a self-propelled steam engine or locomotive. In Feb. 1804, a locomotive built by Trevithick ran on a tramroad in Wales, but these and subsequent experiments were unsuccessful, probably because the weight of the locomotive broke the rails. In 1808 Trevithick exhibited a locomotive and carriage on a circular track in London, but it was regarded as an amusement and not taken seriously.

Following Trevithick's pioneering, the first practical and successful locomotive was built in 1812 to the instructions of John Blenkinsop, an inspector at Middleton colliery near Leeds. It ran on cast iron rails and had two vertical cylinders driving two shafts geared to a toothed wheel which engaged a rack rail. Three further locomotives were built in 1812 and 1813 and used between the colliery and Leeds, a distance of three and one-half miles.

In 1813, William Hedley built "Puffing Billy," a simple adhesion locomotive (*i.e.*, one that relied on friction between wheels and rails, dispensing with the toothed rack rail). It was used for hauling coal trucks between Wylam colliery and the wharves at Lemington-on-Tyne, a distance of about five miles. In the following year George Stephenson, pioneer railway and locomotive builder, completed his first engine, the "Blücher." It was put to work at Killingworth colliery.

In 1823, Stephenson was invited by Edward Pease to build and equip a railway from Stockton to Darlington. This was completed in 1825 and ceremonially opened on Sept. 27 of that year. It was the first public railway in the world that employed locomotive traction and that was intended to carry both freight and passengers, and as such it marked the birth of the public service railway. It was not the first public railway, this honour going to the Surrey Iron Railway company, which was created through an act of parliament passed in 1801; it was opened in 1803 between Wandsworth and Croydon, using horses. In 1804 the Oystermouth railway was incorporated and this became the first railway to carry fare-paying passengers (March 1807), horse traction being used.

During the first two years of its existence, steam traction proved unreliable and expensive to maintain on the Stockton and Darlington railway. The first locomotive was "Locomotion" (now preserved at Bank Top station, Darlington). This and similar machines were only suitable for hauling low-speed mineral trains, and their tractive effort and weight were limited by the comparatively weak track. At times the railway reverted to horses, but the situation was improved with the introduction in 1827 of the "Royal George," a six-coupled locomotive designed by Timothy Hackworth. This and other locomotives eliminated the use of horses in rail freight service by 1833.

In 1829 the Liverpool and Manchester railway held a contest to decide upon the best kind of traction to use and it was won by Stephenson's "Rocket" (now preserved at the Science museum, London). The success of the "Rocket" was due principally to the use of a multiple fire-tube boiler in place of the single-flue boilers previously used. The Liverpool and Manchester railway was opened on Sept. 15, 1830, and it became the first public railway

on which all traffic was hauled by steam locomotives. At this time another great stride was made in track construction by Blenkinsop's patent for fish-bellied rolled-iron edge rails (1829). These were much stronger than cast iron rails and enabled heavier locomotives to be used.

A. RAILWAYS IN THE UNITED STATES

Paralleling this early English development, interest in railways began to develop in the United States, as well as in other countries. One of several horse-drawn tramways built early in the 19th century was Gridley Bryant's Granite railway in Quincy, Mass. Horses supplied power for this three-mile, broad-gauge line, which carried the granite used in building the Bunker Hill monument.

By 1813, the inventor Oliver Evans was proposing a railway between New York and Philadelphia. Two years later, John Stevens received from the New Jersey legislature the first charter for a railway ever granted in America. However, Stevens was ahead of his time: the chartered line, between the Delaware and Raritan rivers, was never built. But in 1825, Stevens built and operated the first locomotive to run on rails in America. It ran on a half-mile circle of track at Stevens' home in Hoboken, N.J.

This was the year that the Stockton and Darlington line opened in England; the success of that pioneering enterprise helped overcome the opposition and apathy toward railways in the United States. On Feb. 28, 1827, the Baltimore and Ohio Railroad company (B. & O.) was chartered (in the following, abbreviations or names in parentheses are those by which U.S. lines are commonly known). The line began carrying revenue traffic Jan. 7, 1830, and the first 13 mi. of line, from Baltimore to Ellicott's Mills (now Ellicott City) opened on May 24, 1830.

The B. & O. was the first railway in the U.S. to be chartered as a common carrier of freight and passengers. Moreover, its promoters looked beyond purely local needs. They envisaged a line going all the way to the Ohio river to channel the commerce of the growing middle west through the port of Baltimore. By 1834 the B. & O. had built to Harpers Ferry, Va. (now W.Va.), and on Dec. 24, 1852, it reached the Ohio river at Wheeling. Subsequently the B. & O. expanded, both through new construction and by acquiring other railways, until it reached Chicago, St. Louis and the Great Lakes.

Almost simultaneously, several other early U.S. railways came into being. Construction of the 5-ft. gauge line from Charleston to Hamburg, S.C., by the South Carolina Canal and Rail Road company began in Feb. 1829. On Dec. 25, 1830, this line became the first in the United States to start scheduled passenger operations using a steam locomotive. When the entire line to Hamburg was completed in 1833, it was the longest then operating in the U.S. (136 mi.). Ultimately, the original Charleston-Hamburg route became one segment of the 8,000-mi. Southern Railway system.

Still other railway systems that later grew into giants of the U.S. railway industry had their beginnings in the decade of the 1830s. The Mohawk and Hudson, first predecessor of the New York Central system, operated its first train between Albany and Schenectady, N.Y., on Aug. 9, 1831. Predecessors of both the Boston and Maine railroad and the New York, New Haven and Hartford Railroad company (New Haven) started regular service in the summer of 1835. Three local lines chartered in Virginia evolved into major rail systems. One was the Richmond and Petersburg, chartered in 1836, oldest element of the Atlantic Coast Line Railroad company. The Portsmouth and Roanoke, pioneer segment of the Seaboard Air Line Railroad company, dates from 1832. The Chesapeake and Ohio Railway company (C. & O.) had its beginning in the little Louisa railway, chartered in 1836.

The Richmond, Fredericksburg & Potomac Railroad company, which operates between Richmond, Va., and Washington, D.C., was incorporated Feb. 25, 1834. It is the oldest American railway that has continued to exist since the beginning under its original name, and without reorganization.

By 1840 there were 2,800 mi. of line in the U.S., and the country had entered its first great era of railway building. Twenty years later, on the eve of the American Civil War, the country had more than 30,000 route miles of track.

With but few exceptions (such as the B. & O.), early railways were purely local in character. They were designed to promote the commercial interest of local communities or areas. As growth progressed, however, many of the small roads were consolidated, forming through routes that served fairly large territories, and new railway projects became more ambitious. The Pennsylvania Railroad company completed its line from Philadelphia to Pittsburgh in Dec. 1852, using ten inclined planes to climb over the Allegheny mountains. A little more than a year later, it completed an all-rail route.

1. The Westward Movement.—By the 1850s U.S. railways were taking on their historic role as civilizers of the western frontiers. The first locomotive in Chicago, the "Pioneer" of the Chicago and Galena Union, now the Chicago and North Western railway (North Western), made its initial run on Oct. 25, 1848—and Chicago was on the way to its ultimate destiny as the nation's largest rail centre.

Soon railways were pushing west from Chicago. The Chicago and Rock Island, now the Chicago, Rock Island and Pacific Railroad company (Rock Island), was the first railway to link Chicago with the Mississippi river (1854). It also built the first bridge across that river. Other pioneer lines built west from the Mississippi. The first locomotive to operate west of the river made a five-mile run from St. Louis in Dec. 1852. This was on a short railway that became part of the Missouri Pacific Railroad company. The Hannibal and St. Joseph, now part of the Chicago, Burlington and Quincy railroad (Burlington), reached the Missouri river in 1859.

The Civil War slowed, but did not stop, the headlong growth of railways in the U.S. After the close of that conflict, another era of intensive railway building began, and it continued into the early years of the 20th century. It reached its high point during the decade of the 1880s, when some 70,000 route miles were laid. In 1882, the greatest single year of railway building in the U.S., 11,569 mi. of track were completed.

Highlighting this era was the completion of several lines—the transcontinentals—which, more than any other factor, helped make the United States finally a truly united nation. On May 10, 1869, the first transcontinental route was created when the Union Pacific Railroad company, building west from Omaha, Neb., met the Central Pacific, now part of Southern Pacific (S.P.), which was built east from Sacramento, Calif. In 1881 the Atchison, Topeka and Santa Fe railway (Santa Fe) joined rail with the S.P. at Deming, N.M., to form the second transcontinental route. Ultimately, there were about nine major routes leading from the middle west or south to the west coast. From Chicago, the Santa Fe and the Chicago, Milwaukee, St. Paul & Pacific (Milwaukee road) run all the way to the west coast over their own rails. The S.P. has its own trackage from New Orleans, La., to Los Angeles, Calif., and on up the coast to Portland, Ore.

2. Land Grants.—A feature of the post-Civil War railway building era was government aid to a number of lines through land grants, loans and other types of assistance. About 131,000,000 ac. of public land were granted to 29 railways for about 18,000 mi. of line. These grants (about 8% of the total U.S. railway mileage) made it possible for the railways to push their lines across prairies and mountains that were then almost entirely undeveloped and very sparsely settled.

Actually, railway aid was, on balance, a profitable activity for the U.S. government. For instance, the government received about \$167,000,000 in principal and interest from the \$65,000,000 it loaned to six pioneer Western railways. The original value of the land grants was about \$130,000,000, but in return the railways agreed to carry government traffic at reduced rates. By the time this agreement was abrogated in 1946, the railways had paid back to the government, through these reductions, more than \$1,000,000,000.

3. Railway Regulation.—For almost 50 years after their beginnings, railways in the U.S. were subject to little governmental regulation. But after the Civil War, abuses such as rate wars, rate discrimination and financial piracy became more widespread. In these things railways were probably no worse offenders than

many other businesses of that era, but since they had by then attained almost a monopoly over domestic transportation, the public could not tolerate these abuses.

Regulation at first was largely at the state level, but public sentiment resulted in the passage, in 1887, of the Interstate Commerce act, which placed the railways under federal regulation. Later, other acts broadened and extended the areas of federal regulation so that the railways finally had to clear through the Interstate Commerce commission almost all proposals for changes in such matters as financing, equipment standards, signaling and rates.

4. Labour Relations.—Railways were one of the first U.S. industries in which employees became unionized. Today there are nearly two dozen "standard railroad labour organizations" which represent employees in various classes or crafts. In 1888 the U.S. congress passed legislation providing, among other things, for special presidential emergency boards to investigate disputes. Through the years, other legislation was added. Labour-management negotiations now are conducted under the complex provisions of the Railway Labor act. Enacted in 1926 and subsequently amended, it provides a national mediation board that has power to mediate disputes, and a national railway adjustment board, composed of management and union representatives, which considers grievances, interpretations and applications of the complicated labour-management working agreements.

Over the years, relations between railway labour and management in the U.S. have been marked with few industry-wide work stoppages—although there were violent and bloody strikes in 1877 and 1894. A brief nationwide strike also tied up U.S. lines in 1946. (See also LABOUR LAW.)

5. U.S. Developments to World War II.—By the early years of the 20th century, railway building had slowed in the United States, and the network had reached about its fullest extent. This was a period of improvements in railway plant and equipment; emphasis was on standardization of equipment and operating techniques.

After a brief period of government control during World War I, the U.S. railways entered an era of further operating refinements but of few spectacular advances, although several technological developments that later had vast impact, among them the diesel locomotive, were being tried. The first inroads of highway competition were being felt. The economic depression, beginning in 1930, dealt the railways a disastrous blow, and many companies went through bankruptcy proceedings. Emerging from this depression decade, U.S. railways faced their supreme challenge, the years of World War II.

6. U.S. Railways in War.—Almost from the first, some military men recognized the value of railways. An early proposal called for a network of railways to be built in the U.S. primarily for military purposes. In many other countries, some or all of the railways originally were constructed strictly for military reasons.

Although some use was made of railways in the Crimean and Mexican wars, the American Civil War was really the first "railway war." Since then, nations in every major war have depended on railways as basic transportation either in the active theatres—as in Europe during the world wars—or to supply men and materials to seaports for overseas shipment, as in the case of the U.S. during those wars.

Experience has shown that railways can move huge quantities of supplies and troops over land with a tremendous economy of fuel and manpower—a vital advantage, of course, during a war emergency. Moreover, railways, while seemingly vulnerable to enemy action, can be more quickly restored to full-capacity operation than any other form of land transport. This was amply demonstrated in World War II and in the Korean war of 1950–53.

At the very beginning of the American Civil War, railways played a key role. The Confederate victory at the first battle of Bull Run (Manassas) was due in considerable measure to the Manassas Gap railway, which was able to deliver a number of reinforcements to the battlefield just in time to turn the tide. Throughout the war, the Confederacy was able to use its railways to concentrate troops where needed and thus help to overcome its

numerical disadvantage. However, the Confederacy was not able to exercise effective organized control of its railways so they could operate to best military advantage.

On the other hand, the Union side was able to organize its military railway operations more effectively. This, along with its better-developed railway network and the fact that most of the U.S. locomotive and car-building plants were in Union territory, played an important part in the final outcome of that conflict.

One of the important lessons learned in the Civil War was that railway cars must be used only for the movement of troops and supplies—not for storage. By World War I this lesson had been forgotten, however. Cars were loaded and sent on their way with no place to unload them. As a result of this practice, congestion approaching paralysis hit the U.S. railway system in 1917. In order to unravel the tie-up, the U.S. government took over the operation of the railways on Dec. 28, 1917. The lines were restored to private operation March 1, 1920.

No such problem arose in World War II, when the U.S. railways demonstrated how efficiently a well-run system can operate to handle extraordinary traffic movements. In the war year of 1944, freight ton-miles were two and one-half times the level of 1938; passenger-miles had increased fourfold. This tremendous traffic was handled with only relatively modest increases in the supply of locomotives and cars. Moreover, this wartime job was done at a time when the railways had supplied some 40,000 officers and men for army transportation corps units and another 300,000 employees were in other branches of the armed services.

During the World War II period, U.S. railways carried almost 98% of all military personnel moving in organized groups and more than 90% of all military freight handled by inland transportation. In the Korean war of 1950-53, the railways performed a similar job on a smaller scale while at the same time handling normal civilian transport requirements.

In the Korean war, too, the flexibility of railways under front-line conditions was reaffirmed. Neither the UN or Communist forces could permanently disable the other side's strategic rail lines even under the impact of heavy air strikes.

B. RAILWAY GROWTH IN CANADA

The growth of Canadian railways paralleled somewhat that of lines in the United States.

Construction of the first line, between Laprairie and St. Johns, Que., began in 1835; its first train operated on July 21, 1836.

By 1860 there were about 2,000 mi. of railway line in Canada. One of the terms on which British Columbia entered the confederation in 1871 was the construction of a transcontinental route. This line, the Canadian Pacific, was completed in 1885. It is literally the tie that bound Canada into a unified nation.

Two other transcontinental lines reached the Pacific coast in 1914 and 1915. They were the Grand Trunk Pacific, which reached Prince Rupert, B.C., in 1914; and the Canadian Northern, built into Vancouver in 1915. Both of these lines were built with government assistance.

The dislocations of World War I dashed the hopes of internal development that had sparked the construction of these two transcontinentals. They required further government financial help and were finally taken over by the dominion government. In 1923 both the Grand Trunk and the Canadian Northern, along with other railways always owned by the dominion, were unified, forming the present Canadian National railways (C.N.R.) which have connections with U.S. railways.

In normal years the Canadian Pacific operates at a profit; the Canadian National, which has many lines serving as yet sparsely settled areas, usually records a deficit. The C.N.R. also serves as an agency of national policy. As a result it has built a number of lines to open up new territory during the years since World War II. One of the more important of these was the Great Slave Lake railway, running 432 mi. from Peace River, Alta., to Hay River and Pine Point, N.W.T.

Other Canadian railways were being built or extended as the dominion entered a period of rapid economic growth. The Que-

bec, North Shore and Labrador, a 320-mi. ore-carrying line from the iron ore deposits near Schefferville, Que., to the St. Lawrence river at Sept Iles, was opened in 1954. In 1958 the Pacific Great Eastern railway (P.G.E.) completed its line all the way from Vancouver, B.C., to Dawson Creek and Fort St. John, B.C., where it connects with the Alaska highway.

C. UNITED STATES AND CANADIAN RAILWAYS AFTER WORLD WAR II

For about a century, railways were the dominant form of inter-city transportation in the United States and Canada. Indeed, their monopoly was almost complete, with the exception of a fair volume of water transport, including river, Great Lakes and inter-coastal.

But the development of the internal-combustion engine and its application to highway vehicles (starting about the beginning of the 20th century) and the invention of the airplane were to have far-reaching effects on railway transportation. In the period between the two world wars, highway transportation of goods by motor truck and of people in buses and private automobiles was already seriously cutting into railway business, especially on branch and secondary lines.

The demands of war hastened the technological development of these new forms of transportation, and by the late 1940s their inroads had reached critical proportions from the railway point of view. Competing forms of transport were continuing to gain in relative volume at the expense of the railways in the early 1960s. This trend was especially pronounced in the United States, where the growth of highways, aviation facilities and pipelines was particularly intense, but the same trend was noticeable—though in its earlier stages—in most other countries except those that were still in the more primitive stages of economic development.

How did the railways react when confronted with this new competition? Accustomed to competing only with other railways, most found it hard to adjust their thinking—and their operations—to meet the challenge of competitors who could offer the public faster, more flexible or, in some cases, cheaper service; and who in most cases were burdened much less by government regulation. Thus for many years motor trucks, automobiles, buses, waterways, airplanes and pipelines took over increasing volumes of traffic against very little resistance from the rail lines. Only the overall growth of the U.S. economy prevented the railways from suffering a drastic absolute—as well as relative—drop in traffic volume.

Eventually, however, railways began to fight back against their new competitors. They took measures to improve the speed and regularity of their train services; offered passengers and shippers new types of equipment; and adjusted their rates to become more competitive—and to more fully reflect the advantages of railroad transportation for high-volume, long-haul service.

The substitution of diesel for steam locomotives in the U.S. and Canada allowed freight and passenger trains to operate at higher sustained speeds. Moreover, the running gear of modern freight and passenger cars (wheels, springs, journal bearings and brake equipment) allows greatly increased top speeds.

The big problem in freight service continued to be the delays encountered in classification yards and freight terminals through which cars must pass. Much has been done to alleviate yard delays by constructing classification yards that are largely automatic. These new yards can sort out freight cars and make up new trains in much less time than was possible in the past.

Railroads are offering their customers special types of freight cars, designed to permit them to load particular commodities quickly and at minimum expense. Typical are the automobile-parts cars with specially designed racks that allow fast loading of specific automobile components; or the covered hopper cars for bulk handling of commodities such as phosphates, cement or flour. Both special and conventional types of freight cars are becoming larger to take advantage of the economies of high-volume shipment.

Significant, too, was the increase in the use of highway trucks by railways. Under governmental restrictions, U.S. railroads could

The "Rocket," built by George Stephenson. It was the winner of the 1829 trials by the Liverpool and Manchester railway, England

Richard Trevithick's "New Castle," 1803, the first locomotive in the world to do actual work

The "Stourbridge Lion," built in England and shipped to the U.S. where it was placed in operation in 1829

The "Best Friend of Charleston," first locomotive built in the U.S. for regular service on a railway. It began scheduled passenger service in 1830 from Charleston, S.C., over a route which eventually became part of the Southern Railway system

HISTORIC LOCOMOTIVES OF ENGLAND AND THE U.S.

The "General," active during the American Civil War. This locomotive was the basic type of the American class (4-4-0 wheel arrangement), a design which continued in service until the 20th century

Engine 999 of the Empire State Express, New York Central railroad, a somewhat later version of the 4-4-0 type. It set a speed record of 112.5 m.p.h. in 1893

Mikado (wheel arrangement 2-8-2), a heavy-duty freight locomotive of the U.S.

Decapod class (2-10-0) locomotive of Germany, a typical freight engine widely used in Europe

Beyer-Garratt articulated type (4-8-2-2-8-4), a unique design with its weight spread over considerable length and also capable of operating over railroads with sharp curves. Used in Africa, Asia and Australasia

Hudson or Baltic type (4-6-4), used extensively on U.S. lines for high-speed, heavy-duty passenger hauling during the steam locomotive era

Pacific (4-6-2) of the French railways, typical locomotive of the years between World War I and World War II

Another Pacific, the British "Britannia" class, a standard type used after World War II

A U.S. "streamliner," a modification of the Northern or Niagara (4-8-4), a final stage of development of steam locomotives for passenger service

The "Big Boy" (4-8-8-4) of the Union Pacific railroad (U.S.), considered to be the largest steam locomotive ever built. Used for hauling freight in mountainous areas

STEAM LOCOMOTIVES

Three DL-600 locomotives, 2,400-h.p. modern diesel-electric units powered by 16-cylinder engines. Santa Fe, U.S.

Gas-turbine locomotive of the Union Pacific railroad, an 8,500-h.p. unit which can develop high speeds with heavy trains such as the long freight shown in the photograph

Diesel rail car of the French railways, a self-propelled passenger unit equipped with a domed observation section

Diesel-hydraulic type, the V200, a 2,000-h.p. locomotive of the German Federal railroad

TE-3, part of a twin-unit diesel-electric of the Soviet railways. Each of the C-C type articulated units is equipped with a 2,000-h.p. engine

Diesel locomotive unit of a Trans-Europ express (T.E.E.) train. T.E.E. trains serve eight nations on international runs. They are operated jointly by the Dutch, Swiss, German, French and Italian railways

Self-propelled rail diesel car (R.D.C.) powered by a pair of 300-h.p., 6-cylinder diesels. Individual units can be joined to make up longer trains

DIESEL, GAS TURBINE AND OTHER SELF-PROPELLED UNITS

BY COURTESY OF (TOP LEFT) ALCO PRODUCTS, INC.; (TOP RIGHT, CENTRE RIGHT BELOW) GERMAN FEDERAL RAILROAD. (CENTRE LEFT, UNION PACIFIC RAILROAD, (BOTTOM RIGHT) NEW HAVEN RAILROAD FROM ASSOCIATION OF AMERICAN RAILROADS; PHOTOGRAPHS, (CENTRE RIGHT ABOVE) SOVFOTO, (BOTTOM LEFT) AUTHENTICATED NEWS

Sliding-door boxcar permitting loading and unloading from both the top and the sides. German Federal railroad

"Big John," 97-ton capacity aluminum hopper car, used by the Southern railway for carrying bulk commodities. Left, a conventional 70-ton capacity covered hopper car

A 30,000 gal. capacity tank car designed to carry a variety of liquids such as chemicals, acids, vegetable oils, and petroleum products

Flatcars in the "piggyback" service of the Santa Fe railway. Each flatcar is carrying two 40-ft. truck trailers

Gondola car owned by the French National railroads, but operated as a unit in the Europ freight car pool, cooperative plan of the International Union of Railways

Specialized flatcar with low central section designed to carry electric power transformers and maintain clearance in tunnels and under low bridges. The car is also unusual in its arrangement of eight axles

Modern automobile carrier of the U.S. railways, a flatcar equipped with two extra decks to accommodate a total of 12 automobiles

German automobile carrier, a two-decked, five-axle type which will hold 10 compact cars

FREIGHT EQUIPMENT

First Pullman sleeping car, a converted day coach which went into service in Sept. 1859

ETR 300 "Settebello," a high-speed electric passenger train of the Italian State railways. Unique design provides passengers with an observation area in the first car while the engineer operates the train in a "blister" cabin above

Interior of the "North Coast Limited," a luxury train of 1900, Northern Pacific railway. It was the first electric-lighted train of the U.S. northwest

Interior of an air-conditioned dining car of the Swedish national railways

First-class compartment, express train of the German Federal railroad

Three-bed sleeping compartment, tourist class, of the Wagon-Lits company which operates passenger equipment on railways of Europe, Africa and the middle east

Master bedroom of the "California Zephyr" of the Chicago, Burlington and Quincy railroad. It accommodates six passengers by day and has four beds (one not shown)

not (for the most part) operate truck lines except as supplements to or in substitution for railway service. Thus railways used trucks to deliver small-lot (less-than-carload, or L.C.L.) shipments from rail car terminals to consignees in nearby areas, and to pick up L.C.L. freight for subsequent rail movement. In some cases, also, railway-operated trucks substituted for trains in local freight service or on branch lines where the volume of business no longer justified train operations.

1. The "Piggyback" Development.—As early as the 1920s, a U.S. railway was carrying loaded highway trucks on flatcars (although the idea dates back to the 19th century). "Piggyback" combines the flexibility of truck pickup and delivery with the economy of rail movement between cities. Piggyback did not begin to grow rapidly until the later years of the 1950s, but some authorities estimated that piggyback traffic might eventually amount to one-half of the total volume of railway traffic.

Along with piggyback, there was increasing interest among railways and other modes of transport in "container" systems. Clearly, the trend was toward a system of freight transport in which merchandise could be loaded into standard containers or boxes, which then would move either via highway on a truck chassis, via rail on special container cars, in ships especially equipped to handle them, or even by air. A single shipment might use two or more modes of transport in the course of its trip. Railways in the U.S. used containers on a small scale in the 1920s, but not until the early 1960s did the technique meet with widespread acceptance.

Future development of piggyback, and containers, could result in a freight transportation system that was quite highly integrated. Each mode of transport might then perform the type of service for which it is best suited, and a single shipment might be moved by several different modes of transport at minimum extra cost.

2. Passenger Service.—In the United States and Canada, long-haul railway passenger service appeared in the 1960s to have a limited future. A vast network of paved highways and the fantastic growth in automobile ownership had diverted almost 90% of all intercity travel to the public automobile. The remaining travel volume was shared by railways, by buses on the public highways and by the rapidly growing air lines.

The greatest area of usefulness for intercity rail travel in the future appeared to be for trips ranging up to 300 mi. between large centres of population; for overnight sleeping car service between large cities 500 to 1,000 mi. apart; and for some commuter service centring on the larger cities. There also appeared to be a market for a limited volume of long-haul railway service in luxury "cruise" trains.

D. RAILWAYS OF MEXICO AND CENTRAL AMERICA

The railway systems of Mexico and in Central and South American countries are less advanced than those in the U.S. and Canada. Except in Mexico, most countries have a predominance of narrow-gauge lines of relatively light construction.

The Mexican railways, almost all of which are owned by the federal government, have a route mileage of approximately 13,000. Of this approximately 8,100 mi. is operated by the National Railways of Mexico (Ferrocarriles Nacionales de México). The N. de M. was acquired both by purchase and expropriation, beginning in 1937. Prior to that time much of the railway development in Mexico had been by private interests.

Most of the Mexican railway mileage is standard gauge, and there are interchange connections with U.S. railways at several points. As a result, the Mexican railway network may be said to be integrated with those of the U.S. and Canada to a considerable extent. Since World War II a vigorous modernization program has been under way.

The railways of Central America are all narrow gauge and of light construction. Some of them are government owned; others are private railways owned and operated by banana companies. There is little integration: most of the lines are isolated and serve only small areas. Cuba has about 2,900 mi. of public service railways and another 7,000 mi. of sugar mill railways operated by 175 different mills.

E. SOUTH AMERICAN RAILWAYS

South America has about 66,000 route miles of railroad, of which about 62% is narrow gauge. The rest is either standard or wide gauge. Although early development of South American railways, beginning in the middle of the 19th century, was largely by private enterprise, there later was a trend toward government ownership and operation. This was particularly marked in Argentina, where in 1945 only about 31% of the trackage was state owned; by the 1960s Argentina's 27,600 mi. of line were all under the jurisdiction of the Argentine State railways.

Brazil is a close second to Argentina in total track miles. Of its 23,253 track miles, all but 2,980 are owned by state or federal governments.

There is little integration of railways in the South American countries. This is due partly to the rugged terrain over which many of them operate but even more to the diversity of gauges, as well as equipment standards. Many early South American railways were built by British, French, U.S. and German concerns and this resulted in considerable variation in the types of equipment, methods of operation and even terminology.

Nearly all South American railway systems had improvement programs planned or under way in the 1960s, but most were handicapped by lack of funds.

F. EUROPEAN AND ASIAN RAILWAYS

1. Great Britain.—The success of the Stockton and Darlington and the Liverpool and Manchester lines touched off widespread railway construction in Britain. In 1836, the opening of the London and Greenwich railway brought the first public passenger service to London. In 1838, the London and Birmingham railway was opened throughout its length and in 1840 the line from London to Southampton was completed. The Great Western railway's 7-ft. broad-gauge line from London to Bristol was opened to traffic in 1841.

Between 1844 and 1846 parliament authorized the construction of over 400 railways. This represented the height of what was known as the railway mania, and there followed a period of slower development and a growing number of consolidations. Early in the 1900s some systems realized that mergers could create a stronger economic position for them, but because of monopoly fears, acts sanctioning such moves were not passed by parliament.

Amalgamation of Lines.—Following World War I, it was evident that large-scale consolidation was a financial necessity, and the government decided upon compulsory amalgamation. As a result of the Railways act of 1921, some 123 separate railway companies amalgamated into four main groups on Jan. 1, 1923. The four systems were the London, Midland and Scottish railway; London and North Eastern railway (L. & N.E.R.); Great Western railway; and Southern railway. Certain minor railways and London's Underground retained their separate existence. The latter were amalgamated with London area bus and tramway systems in 1933 under authority of the London Passenger Transport board, a public body constituted by act of parliament.

The object of creating four large railway systems was to consolidate control and obtain more economical methods of operation. The consolidation also allowed the introduction of a new classification of rates and charges designed to enable the railways to earn a standard revenue.

During the 1920s the railways began to suffer from increased highway competition. To combat this, various new services were introduced. In 1928, an act of parliament authorized the railways to operate both passenger and freight road services, and they acquired extensive financial interests in existing undertakings, principally bus companies.

Despite competition and the general economic depression of the 1930s, the four railway companies were responsible for some remarkable achievements between 1925 and 1939. In 1928 the L. & N.E.R. began the nonstop running of its principal express train between London and Edinburgh, a distance of 392½ mi. The high-speed running of streamlined passenger trains began in 1935 with the introduction of the "Silver Jubilee" between London and Newcastle. It was followed in 1937 with the "Coronation" (Lon-

don-Edinburgh) and the "Coronation Scot" (London-Glasgow).

At the outbreak of World War II in 1939, the railways were placed under government control. Co-ordination and direction were through the Railway Executive committee, appointed by the ministry of transport. During the period 1939-45 the railways operated 260,000 special troop trains and 280,000 matériel trains for the armed services. Over 9,000 incidents of enemy action were recorded on the railways and nearly 400 railway men were killed and 2,444 injured by enemy action. At the end of the war the state of the railways had deteriorated considerably due to lack of maintenance, abnormal wear and tear, shortage of personnel and damage through enemy action.

Railway Nationalization.—In 1946 a bill was introduced in parliament for setting up a publicly owned inland transport system. Under the Transport act, which became law on Aug. 6, 1947, the British Transport commission (B.T.C.) was established as the body responsible for taking over the railways, the railway owned docks, road haulage contractors, many road passenger undertakings and the inland waterways. On Jan. 1, 1948, the nationalization of the railways took effect and they became British railways. The Railway Executive committee became the body responsible to the Railway commission for the management and co-ordination of British railways. The latter were divided, on a geographical basis, into six regions: Eastern, Northeastern, Western, Southern, London Midland and Scottish.

A transport bill which became law on May 6, 1953, provided for greater decentralization of the railways. The Railway Executive committee was abolished and the chief regional managers were made responsible to the commission. The greater degree of autonomy enabled the regional officers more closely to meet the needs of the local traveling public and trading interests.

On Jan. 24, 1955, the B.T.C. announced an extensive and ambitious modernization and re-equipment plan. The plan aimed at producing a really modern system that would be able to meet both current traffic requirements and those of the foreseeable future. It was intended that the main features of the plan would be started within 5 years and completed within 15 years. The main objective was to provide "an equipment, in the widest sense of the word, of modern design and fit to give reliable and speedy transport service on a large scale." The plan involved an outlay of approximately £1,200,000,000.

The modernization plan began to show concrete results in 1958, although no large scale improvements had, by that time, been completed. In 1959 there was a reappraisal of the plan, aimed at accelerating certain portions of it. In 1958 there was a total deficit for the year of £89,000,000, covering all the commission's activities. To meet the situation the government agreed to increase the limit of deficit borrowing from £250,000,000 to £400,000,000, as well as to increase the general borrowing powers. By the early 1960s the total deficit for the British railways had reached about £160,000,000.

An act of parliament in 1962 dissolved the British Transport commission and replaced it with the British Railways board, which took over administration of the system on Jan. 1, 1963. Later in that year the newly formed board proposed measures to bring the railway system into line with present and future requirements. The main features of the proposals were:

The closing of many branch lines and a reduction in the number of passenger stops.

A reduction in the number of freight depots, those remaining to be linked by express freight services.

Development of a network of high-speed, "containerized" freight services, called Liner Trains, between key centres.

Movement of the bulk of coal and mineral traffic in block trains (called unit trains in the U.S.), each of which would carry only one type of material.

Reduction in the freight and passenger car fleets.

Replacement of the remaining steam locomotives by diesels.

The board announced that the original modernization plan would continue, but with modifications to adapt it to the new program.

In 1957 the B.T.C. (railway merchandise) Charges Scheme came into force, allowing freight charges to be varied below the permitted maximum. This enabled the railway to charge on the basis

of loadability, except for consignments of 100 tons or more, for which charges had to be reasonable.

Passenger Service.—Passenger train developments included the widespread introduction of diesel, multiple-unit, rail-car trains; some 4,000 of these were operating throughout Britain in the early 1960s. In 1960 a number of luxury diesel-Pullman services were introduced, and these later were widely extended. Many passenger schedules were accelerated, and the speed limit over certain sections of line was raised to as much as 100 m.p.h. In 1955 a new type of service aimed at the motorist was begun. Called the "Car-Sleeper Limited," it carried automobiles in specially designed cars, their drivers and passengers traveling in sleeping cars. It operated between London and Perth and, following its success, a network of similar services was introduced to serve other cities.

Electric Traction.—Electric traction is used extensively in southeast England, together with suburban lines in various parts of the London area and around Manchester and Liverpool. All these use direct current and all but one use current collection via a conductor rail mounted alongside the running rail. Electrification of the line connecting Manchester, Sheffield and Wath was completed in 1954. This uses the 1,500-v., D.C. overhead conductor wire system. The same system was employed for the electrification of the London-Shenfield line, which was completed in 1949 and extended to Southend in 1956 (this, however, was later converted to A.C. to bring it into conformity with later electrification projects in the same area). In 1956 it was announced that future electrification would be on the 25-kv., 50-cycle, A.C. system. The first application of this form of electric traction was on the Colchester-Clacton-Walton line, some 24½ route miles (inaugurated in 1959). The first trunk route to be electrified using 25-kv. power was to connect London, Manchester and Liverpool.

2. China.—Following creation of the People's Republic of China in 1949, an intensive program of rehabilitating war-damaged lines and constructing new ones was started. Among the new lines were the Ch'eng-tu-Chungking railway, opened in 1952, and one connecting Mongolia and China, opened in 1955. There was some 5-ft. gauge line adjoining Russian territories and also some narrow-gauge mileage; however, the majority of the system was standard gauge. Through passenger train services were being operated between Peking and Moscow; Peking and Ulan Bator; and Peking and Hanoi.

3. France.—The first railway in France, from St. Étienne to Andrézieux, was officially opened on Oct. 1, 1828, although it was in unofficial use the year before. At first only freight was carried, passenger traffic commencing in 1832. Horse traction was employed until the adoption of steam locomotives in 1832. In 1830 the first section (between Givors and Rive-de-Gier) of the St. Étienne-Lyons railway was opened, and the line was completed in 1832. Both steam and horse traction were used, steam taking over completely in 1844. The first international line from Strasbourg to Basel, Switz., was completed in 1841, by which time France had 350 mi. of railways.

In the 1850s railway construction was at its height and there emerged six principal companies: Nord, Est, Paris-Orléans, Paris-Lyons-Méditerranée, Midi and Ouest. In 1878 the state took over a group of small companies in western France, thus creating the État system. By 1902, the railway network had grown to 28,400 miles.

The Ouest railway became state owned in 1908, and following World War I the Alsace-Lorraine railways also became French property. On Jan. 1, 1938, the five remaining privately owned railways were taken over by the government. They—and the existing État system—formed the French National railways (Société Nationale des Chemins de Fer Français [S.N.C.F.]), a joint stock company with 51% of its capital held by the government.

During World War II the S.N.C.F. suffered extensive damage and by 1944 some 82% of the motive power, 80% of the coaches and 64% of the freight cars had been damaged or destroyed. Extensive damage had been wrought on many other installations, but by mid-1946 nearly all track (24,800 mi.) was restored to use and by mid-1948, 2,491 bridges and viaducts had been rebuilt.

Following the immediate postwar restoration of basic facilities,

the S.N.C.F. embarked on the modernization of its system. Initial recovery was aided by the supply of 1,340 steam locomotives from the U.S. and Canada and 48,000 freight cars from North America and Britain.

The principal features in the modernization of the system were the steady abandonment of steam traction, increased use of diesel power and large-scale electrification. Extensive improvements also were made to track and signaling, and large quantities of new rolling stock were introduced.

The initial postwar project was to electrify the main line from Paris to Lyons, and this was completed in 1952. The prewar 1,500-v., D.C. system was adopted. Further sections from Lyons subsequently were dealt with, and electrification was being continued to Marseilles. The S.N.C.F. also developed the use of 25-kv. A.C. at the commercial frequency of 50 cycles for rail traction.

4. Germany.—The use of the steam locomotive in Germany began on Dec. 7, 1835, with the opening of a railway between Nürnberg and Fürth. Both private companies and states built railways, but after 1876 the privately owned systems were gradually absorbed by the states. By 1909 the total route mileage was 35,625.

In 1920 there was a further change in ownership when the state systems were unified as the German State railways. Their status was changed in 1924 to that of a publicly owned company, but a few years later they again reverted to government ownership.

Following World War II and the partition of Germany, two railway systems emerged. In the German Federal republic (west Germany) there emerged the German Federal railway (Deutsche Bundesbahn or D.B.), while in the German Democratic republic the title of German State railway (Deutsche Reichsbahn or D.R.) was retained. In west Germany, apart from the D.B., there were about 250 public railways owned by commercial concerns, municipalities and provincial governments.

After World War II a great deal of reconstruction was necessary and the opportunity was taken to introduce new equipment. There were improvements in track, signaling, communications, locomotives and rolling stock, and steam traction was being replaced by diesel locomotives and electrification.

5. India.—The most complex railway network in Asia, and also the oldest, exists in what was the dominion of India, now split into the republics of India and Pakistan. In 1849, the East Indian Railway company registered, and the first line to be opened was between Bombay and Thana in 1853. This early development was due to British influence, and the various networks gradually extended and increased in size and scope.

The control of the Indian systems comes under the ministry of railways at New Delhi. There are eight railways, which serve different areas of the country: Central, Eastern, Northern, North Eastern, Northeast Frontier, Southern, South Eastern and Western. The Central railway is principally 5-ft. 6-in. gauge, and the Eastern railway is entirely 5-ft. 6-in. gauge, except for 17 mi. of 2-ft. 6-in. gauge. The Northeast Frontier railway is mainly metre gauge, and the North-Eastern railway is entirely of this gauge. The Northern railway is largely 5-ft. 6-in. gauge, as is the South Eastern railway. The Southern railway is mainly metre gauge, and the Western railway has a majority of metre-gauge mileage, with some 5-ft. 6-in., 2-ft. 6-in. and 2-ft. gauges. The total mileages for the various gauges of the entire network are: 5 ft. 6 in., 16,246; metre, 15,480; and 2 ft. 6 in. and 2 ft., 2,735.

6. Ireland.—The first railway in Ireland was opened Dec. 17, 1834, between Dublin and Kingstown (now Dún Laoghaire). It was originally constructed to the 4-ft. 8½-in. gauge but was converted to the principal Irish gauge of 5 ft. 3 in. in 1857. The first line to be opened in Northern Ireland was the Ulster railway between Belfast and Lisburn in 1839, originally built to a gauge of 6 ft. 2 in., and converted in 1847 to 5 ft. 3 in.

On Jan. 1, 1925, the majority of all lines wholly within the Irish Free State were combined into the Great Southern railways, and on Jan. 1, 1945, this system and the Dublin United Transport company were merged into the Irish Transport company (Córas Iompair Éireann or C.I.E.). The Great Northern Railway board's

facilities in the Republic of Ireland were merged with C.I.E. in 1958.

Under the 1948 Transport act (Northern Ireland), the Irish Road Transport board, the Belfast and County Down railway and the Northern Counties committee were all acquired by the Ulster Transport authority (U.T.A.), and in 1958 the portion of the Great Northern railway board in Northern Ireland was merged with the U.T.A.

7. Italy.—The first railway in Italy was between Naples and Portici, opened in 1839. Railway construction in other parts of the country followed, but it was not until the union of the states of Italy took place in 1861 that the idea of a national rail network could be put into practice. In 1885, the major systems were merged into three railways and in 1905–07 these networks, and other smaller lines, were taken over by the state.

During World War II the system suffered considerable damage and extensive reconstruction was necessary. The electrified network, which dates back to 1901, was restored and greatly extended. The majority of the electrification was 3,000-v. D.C., but there was some 3,600-v., 16½-cycle A.C.; this was scheduled to be converted to D.C.

8. Japan.—Japan's first railway was projected in 1869, but construction did not start until 1870 and the first section, between Shimbashi (Tokyo) and Yokohama was not opened until 1872. The years 1885 to 1895 saw the rapid growth of privately built lines in various parts of the country. In 1906 and 1907, under the Railways Nationalization law, the government acquired 17 of the major private lines, boosting the proportion of government-owned mileage from 32% to 91%.

In 1949 the government railways were reorganized into a public corporation, the Japanese National railways (J.N.R.), which in the 1960s operated about 12,600 route miles of line, most of it 3-ft. 6-in. gauge. There were still about 4,600 miles of private railways, most of them short, but some carrying heavy traffic.

Japan's railways, largely built to high standards, carry a very heavy traffic. J.N.R.'s Tokyo-Ōsaka route (the Tokaido line) in the early 1960s carried the heaviest traffic density on the system (about 60 to 80 passenger trains and 50 to 60 freight trains each way daily). However, the capacity of the double-track, electrified 3-ft. 6-in. gauge line had almost been reached. In 1964, a new double-track, standard-gauge line was opened between Tokyo and Ōsaka, a line that had no grade crossings and was built to permit a top speed of 150 m.p.h. for passenger trains.

9. Norway.—Norway's first railway was completed in 1854 between Oslo (then Christiania) and Eidsvoll. Railway construction has always been difficult because of the mountainous nature of the country, the rigorous climate and the relatively small population. Main lines radiate from Oslo to Bergen, Trondheim, the Swedish frontier and Stavanger. A completely isolated section of the system is the electrified Ofoten railway from the Swedish frontier at Riksgränsen to Narvik; this carries a heavy iron ore traffic. Some other lines are also electrified, the longest running from Oslo to Stavanger (370 mi.) and the total electrified mileage in 1958 was 951.

10. Pakistan.—The partition of India and Pakistan resulted in the latter having two territories, separated by the widest part of India. As a result Pakistan has two distinct railway systems. Eastern Pakistan is served by the Pakistan Eastern railway, which has its headquarters at Chittagong. The majority of its route mileage is metre gauge, with some 5-ft. 6-in. gauge and 2-ft. 6-in. gauge. Western Pakistan is served by the Pakistan Western railway, which has its headquarters at Lahore. It is largely 5-ft. 6-in. gauge, with some metre gauge and 2-ft. 6-in. gauge. There is no electrification in Pakistan, but the use of diesel traction was growing in the 1960s.

11. Spain.—The first railway in Spain was the Barcelona-Mataró line, opened Oct. 28, 1848. The topography of the country made subsequent construction slow and expensive. From the many companies in existence there emerged, through a series of consolidations, four major systems. During the civil war of 1936–39, all the railways suffered damage and their position after hostilities was so difficult that the Spanish National railways (Red

Nacional de los Ferrocarriles Españoles) was formed in 1941, taking control of 7,580 mi. of 5-ft. 6-in. gauge lines in 1943. There is also an extensive mileage of narrow-gauge track in the country, operated by about 50 privately owned systems.

12. Sweden.—The railways of Sweden were built partly by private companies and partly by the state. The first standard-gauge line was opened in 1856 and the first trunk line from Stockholm to Göteborg was inaugurated in 1862. As early as 1879 the state began taking over private companies and in 1939, the Swedish parliament decided that the majority of lines still privately owned should be taken over by the Swedish State railways. As a result some 95% of the railway network had come under state control by the 1960s.

One of the most important aspects of the system is the heavy traffic in iron ore between mines in Lapland and the ports of Narvik, Norway, and Lulea.

13. U.S.S.R.—A gauge of 6 ft. was selected for the first public railway in Russia, which was opened—with horse traction—in 1836. In the following year, steam traction was introduced, with locomotives supplied from Britain. The first line of any length was from Warsaw to the Austrian frontier, opened in 1848, followed by the 400-mi. Moscow-St. Petersburg (now Leningrad) line, opened in 1851; this was of the 5-ft. gauge, which became the standard in Russia. The network spread somewhat slowly at first, gathering momentum from the 1860s onward, until in 1900 there were some 33,000 mi. of line. At the time of the Russian Revolution, route length was 43,800 mi. and there were 25 state-owned and 13 privately owned systems.

Following the revolution, the railways were nationalized and by a series of five-year plans the system was rehabilitated and modernized. World War II resulted in the railways being worked to capacity and, in many areas, being extensively damaged. Postwar reconstruction and modernization included diesel traction, electrification, improved signaling and train control apparatus, and new rolling stock. The railway is the principal form of transportation in Russia and handles approximately 80% of all freight traffic.

The network is split up into 45 railways controlled by railway boards which, in turn, are under the supervision of the ministry of transport and communication.

An important development after World War II was the introduction of dual-gauge passenger coaches which can have the trucks of one gauge exchanged for those of another, using special lifting installations at the break-of-gauge point. This permits the through running of coaches between Russia and east and west Europe.

One of the most notable lines in Russia is the Trans-Siberian railway, 5,787 mi. long, which links Moscow and Vladivostok. Construction commenced in 1891, the work starting simultaneously from the east and west terminals. Originally, passengers could not make the entire journey by rail but had to travel by boat (or, in winter, by sleigh) across Lake Baikal. However, by 1916 a line had been laid around the lake, allowing the entire journey to be made without changing cars.

In 1960 a Trans-Siberian express left Moscow daily, requiring nine days to reach Vladivostok. There also was a through train three times a week between Moscow and Peking.

G. AFRICAN RAILWAYS

Construction of the first railway on the African continent was started in 1852 in Egypt. It was the Alexandria-Cairo line, the first section of which was opened in 1854. It was followed by the opening, in 1860, of a line between Durban and the Point in south Africa. Development of railway mileage in Africa as a whole was slow until the turn of the century, when a number of construction schemes were started. Some other early railway building took place in Tunisia (first line planned in 1875); the Sudan (first tracks of a military line laid in 1897-98); formerly French Equatorial Africa (construction started in 1880); and Tanganyika (construction started in 1891).

1. Republic of South Africa.—In South Africa, the discovery of diamonds at the Cape gave considerable impetus to railway construction. By the time the Union was founded in 1910, some 7,570 mi. of track had been laid, of which the majority was state owned.

There were three systems, the Central South African railways, the Cape Government railways and the Natal Government railways, all of which were merged in 1916. By the 1960s, the South African Railways and Harbours administration had the most extensive network on the African continent. Apart from the operation of the railroads, the administration operates road services, the principal harbours and the South African airways.

2. Central Africa.—The East African Railways and Harbours system was formed in 1948 by the amalgamation of the Kenya and Uganda Railways and Harbours and the Tanganyika Railways and Ports services. Construction of the original Uganda railway was begun at Mombasa in 1895; the site of the present city of Nairobi was reached in 1899 and Kisumu, on Lake Victoria, in 1901. Kampala, the commercial centre of Uganda, was linked with the coast (871 mi.) in 1931 following the completion of a line around the north shore of Lake Victoria and the bridging of the Nile at Jinja. Subsequently, extensions were made to Mityana (1953), Kabagole (1955), Kasese (1956), Gulu (1963), and Mnyusi to Ruvu (1963).

The first line in the Tanganyikan section was completed in 1911, between Tanga and Moshi. The Dar es Salaam line was constructed between 1905 and 1914. A branch from Tabora and Mwanza, on Lake Victoria, was built between 1925 and 1928, after the country came under British mandate. Steam traction predominates, although some diesel locomotives have been introduced.

In 1947 the Southern Rhodesian government purchased the railroad systems in Northern and Southern Rhodesia and the Bechuanaland Protectorate. There are connections with the Congo railway, the Beira railway (Mozambique) and the South African railways. The railway was making growing use of centralized traffic control and it also operated 2,000-h.p. diesel-electric locomotives, some of the most powerful units ever built for 3-ft. 6-in. gauge tracks.

In the Republic of The Congo the principal lines are operated by the Compagnie du Chemin de Fer du Bas-Congo au Katanga (B.C.K.). The first lines to be built were from Sakania to Bukama (1910 to 1918) and Port Francqui to Bukama (1923-28). The Tenke-Dilolo line was started in 1928 and completed in 1931. Another line from Kamina to Kabongo links the B.C.K. with the Compagnie des C. de F. du Congo Supérieur aux Grands Lacs Africains (C.F.L.). The C.F.L. has 596 route miles of 3-ft. 6-in. gauge track from Albertville to Kabalo and Kabongo and from Kabalo to Kindu. A separate 78-mi. metre-gauge line runs from Ponthierville to Stanleyville.

Other 3-ft. 6-in. gauge systems are to be found in Nigeria, Nyasaland, Sudan, Republic of Congo, Ghana and Angola. The majority of the remaining systems are of metre gauge. In former French West Africa ([1] Senegal to Mali; [2] Guinea; [3] Ivory Coast; and [4] Dahomey) there are four lines of this gauge, totaling 2,542 mi., all operated entirely with diesel traction. The railway system in Ethiopia is also metre gauge. The building of the main line from Djibouti on the coast of French Somaliland began in 1897 and reached Addis Ababa in 1917.

3. Northern Africa.—Egypt, the scene of the first railroad in Africa, by the 1960s had an extensive standard-gauge system extending to 2,967 mi., with some narrow-gauge mileage as well. There was also a considerable amount of standard-gauge mileage in north Africa. Post-World War II developments included extensive modernization and the virtual replacement of steam traction by diesel and electric power. There were also other lines of narrower gauges in the country, some of which were being converted to standard gauge.

H. AUSTRALASIAN RAILWAYS

1. Australia.—The first railway to be operated by steam traction in Australasia was a 2-mi. line from Flinders street, Melbourne, to Sandridge (now Port Melbourne). It was built by the Melbourne and Hobson's Bay Railway company and opened on Sept. 12, 1854. In the following year a second line was opened in New South Wales. Construction was originally in the hands of two private companies, but when they experienced financial difficulties they were bought out by the N.S.W. government. The first steam railway in South Australia was opened in 1856. It was

7½ mi. long, of 5-ft. 3-in. gauge, and ran between Adelaide and Port Adelaide. Other parts of Australia did not have the benefits of rail transportation until later.

Unfortunately, in the early days of development each state laid down tracks in whatever gauge it considered most suitable to its needs and finances. Only one state, New South Wales, chose the standard 4-ft. 8½-in. gauge. Victoria and South Australia selected a broad gauge of 5 ft. 3 in. and Queensland and Western Australia chose the narrow 3-ft. 6-in. gauge. This means that freight often has to be transhipped and passengers transferred from a train of one gauge to that of another.

In later years the Commonwealth Government railways built several standard-gauge lines, the longest being the Trans-Australian railway from Port Pirie, South Australia, to Kalgoorlie, Western Australia, a distance of 1,108 mi. A feature of this line is one track length of 300-mi. without a curve, said to be unique in the world. In 1963 a standard-gauge line was opened between Melbourne and Albury that provided, for the first time, through running between Melbourne, Sydney and Brisbane.

After World War II, efforts were made to standardize gauges, but progress was slow. Adding to the gauge problems were those of long distances, sparse population and large concentrations of population in a few large cities.

By 1963, all the principal railway systems were state or government owned.

The Commonwealth Government railways was unusual in Australia in that it was operating profitably, largely because of the adoption of diesel-electric traction. Piggyback transport (road trailers and semitrailers carried on flat wagons) and container traffic also were introduced on the Trans-Australian route to overcome break-of-gauge delays.

2. New Zealand.—In New Zealand the first railway to be operated with steam traction was opened on Dec. 1, 1863, between Christchurch and Ferrymead. It had a gauge of 5 ft. 3 in.

Following the start of this line, numerous others were built by the different provincial governments. These were of various gauges, but in 1870 an act of the general government stated that all future construction should be of 3-ft. 6-in. gauge. In 1876 the provincial governments were abolished and their railways were taken over by the general government and the lines gradually converted to a uniform 3-ft. 6-in. gauge. Between 1885 and 1908 various private railways also were taken over.

The system was faced with strong competition from air and road transport, but it steadily decreased its operating losses. In the 1960s, emphasis was on increased use of diesel power, the installation of long welded rail, increased use of centralized traffic control and the completion (in 1955) of the 5½-mi. Rimutaka tunnel. An unusual operation was the rail-air freight service between the two islands.

The general trend in Australasia was toward the adoption of more modern equipment (particularly diesel traction), electrification where traffic justified it, and improved passenger and freight rolling stock.

II. TRACK AND ROADWAY

1. Railway Location.—Ideally, a railway should be built in a straight line, over level ground, between large centres of trade and travel. In practice, this ideal is rarely approached. In planning, the location engineer must balance the cost of construction against annual maintenance and operating costs, as well as against the probable tonnage to be carried and the revenue it will produce.

Thus, railways in areas of dense population and heavy industrial activity have generally been built for heavy duty—with minimum grades and curvature, heavy bridges and perhaps multiple tracks. This was so in the case of most of the main-line railways of Britain and continental Europe. In sparsely settled country, as in much of the United States during the 19th century, as well as in Canada and South America, railways were built to minimize initial construction costs. As a result, the lines had sharper grades and curves, and were generally of lighter construction. As traffic grew, the main routes were later improved to increase their capacity and reduce operating costs.

2. Gauge.—One of the main cost determinants is the gauge, or distance between the inside faces of the running rails. Generally, the narrower the gauge the less costly is the line to construct and equip. This explains why many of the railways in underdeveloped, sparsely settled countries have been built to narrow gauges. On a narrow-gauge line, curvature can be more severe, less space is required and over-all construction can be lighter. Disadvantages are the limitation of speed because of reduced lateral stability and limitations in the size of locomotives and rolling stock.

Track gauges vary throughout the world from less than 2 ft. to 5 ft. 6 in., and in the past have been as wide as 7 ft.

About 60% of the world's railway mileage is of so-called standard gauge, which measures 4 ft. 8½ in. It is not clear how this odd width originated. One of many suggested possibilities is that it evolved from the wheel spacing of vehicles used on early English wagonways or tramways, which were the predecessors of the modern railway.

Standard gauge got its foothold in North America through the English locomotives imported for some of the earliest U.S. lines. Today, nearly all the railway mileage in North America is standard gauge, although in the early years many lines were built in both wider and narrower sizes.

In Central and South America are to be found extremes ranging from 1 ft. 11½ in. to 5 ft. 6 in. The majority is narrow gauge, although many countries have systems in different gauges—a legacy of unco-ordinated development. Standard gauge, or a width so nearly identical as to allow the through running of vehicles, is found in most of Europe, excepting Finland and Russia (5 ft.), Ireland (5 ft. 3 in.) and Spain and Portugal (5 ft. 6 in.). A considerable mileage of narrow gauges—including metre (39.37 in.), 2 ft. 6 in. and 1 ft. 11½ in.—also exists on the continent of Europe, particularly in Germany, Austria, Spain and Switzerland.

In Africa the principal gauges are 3 ft. 6 in. and 1 m. India and Pakistan both have extensive 5-ft. 6-in. broad-gauge systems, together with a large metre-gauge mileage and narrow-gauge lines of 2 ft. and 2 ft. 6 in. The lines of the Japanese National railways are of 3-ft. 6-in. gauge except for the standard-gauge "New Tokaido" (Tokyo-Ōsaka) line. That country also has a number of short, privately owned railways, some of which are standard gauge, as well as 3 ft. 6 in. The Chinese railways, on the other hand, are laid largely to standard gauge, although there is some 5 ft. and narrow gauge as well. New Zealand employs a gauge of 3 ft. 6 in., but Australia has major networks in three different gauges: 3 ft. 6 in., 4 ft. 8½ in. and 5 ft. 3 in.

The benefits of a uniform gauge were recognized early. It permits free interchange of cars between various railway lines, thus speeding the flow of commerce and, of course, greatly reducing the over-all cost of transporting goods and people. Only because of this virtual uniformity of railway gauge in North America was the railway able to play the dominant role in the settling and development of that continent. Conversely, in areas where uniformity of gauge has not been achieved, such as South America and Australia, development of the railways—and consequently the economic growth of the countries they serve—has been correspondingly slowed.

The principal gauges in use in major countries are shown in Table II. The total route length of all railways throughout the world is 781,000 mi., divided approximately as follows: North America, 36%; Europe, 34%; Asia, 12%; Central and South America, 8%; Africa, 6%; Australia and New Zealand, 4%.

3. Rail.—Railway track as we know it originated in the plateways used in English coal mines, consisting of squared timbers on top of which iron plates were fastened. The earliest examples of iron rail were L-shaped, the upright portion keeping the flangeless wagon wheels running on the flat baseplate. From this developed the I-shaped rail which was carried in pedestals or chairs, these in turn being secured to stone blocks or, later, wooden sleepers or cross-ties. The rails were retained in position in the chairs with the aid of oak keys.

The I-shaped rail led to the bullhead rail, in which the head was of greater area than the foot. The use of this rail in conjunction with chairs attached to wooden ties became the standard for

*Predominant ownership is given; most countries have both private- and state-owned lines.

†Gauge of the principal mileage; most countries have lines of several gauges.

‡Data are for the late 1950s and early 1960s.

the British railway systems until 1949; the weight of rail for main lines was 95 lb. per yard and the length 60 ft. After 1949, British railways were converting to a standard flat-bottomed rail weighing 109 lb. per yard.

In the 1830s a French engineer, Charles Vignoles, invented the flat bottomed rail, which was like an inverted T. It was spiked direct to the tie, which made for simple and inexpensive construction. A further refinement was the introduction, in 1847, of the fishplate which joined the outer ends of the rails together. This stopped the movement of the rail ends beyond the tie.

The majority of continental railways and those in other areas adopted the flat-bottomed rail from the beginning. The standard rail length in Europe is 30 m. (98 ft. 5 in.) and the weight, for main line use, is 118.8 lb. per meter, or about 109 lb. per yard.

Some of the earliest U.S. railways used iron rails shaped like an inverted U, but since iron had to be imported from England, it was very costly. A more common and much less expensive type of construction involved the use of iron straps fastened to the tops of longitudinal wooden stringers. The main problem with these iron straps was their often-disastrous tendency to break loose and slash up through the floors of passing cars.

The modern type of track, using the flat-bottomed T rail on wood cross-ties or sleepers, was tried in the U.S. as early as 1831. The Camden and Amboy Railroad and Transportation company used iron T rails designed by its president, Robert L. Stevens. At first they were attached, with spikes much like those used today, into wooden plugs inserted in stone blocks. Later, during a shortage of the stone blocks, the rails were spiked direct to wooden ties in order to keep the construction going. The emergency wood ties proved far superior. The track was more flexible; it held up better, gave a smoother ride and was much easier on the rolling stock.

It was not long before most of the railways in the U.S. began using this type of construction, although it did not become standard until about 1850 (as late as 1848 the Galena and Chicago Union railroad laid some strap-iron track). Iron rails were used in the U.S. until 1865, when rails of Bessemer steel made their appearance. By the early 1900s U.S. railways were using open-hearth steel rails, which soon largely supplanted Bessemer steel.

Although present-day rail is, in appearance, similar to the early designs of Stevens and Vignoles, it is actually a highly refined product in terms of both engineering and metallurgy. Much study and research have produced rail designs that minimize internal stresses under the weight of traffic, and thus prolong rail life. After they have been rolled at the steel mills, rails are allowed to cool slowly in special cooling boxes. This controlled cooling minimizes internal shatter cracks which at one time were a major cause of broken rails in track.

Hundreds of different rail cross sections were designed for U.S. and Canadian railways, and most of the larger lines used sections of their own design. Many of these rail sections are still in use, but there developed a strong trend toward standardizing on a few sections. The bulk of the new rail being purchased in the 1960s in North America was of sections weighing 100, 106, 115, 119, 132, 136 or 140 lb. per yard. The American Railway Engineering association was studying the possibility of standardizing on perhaps three or four rails of varying sizes for different traffic conditions. The standard U.S. rail length is 39 ft.

In general, lighter rail sections are used in countries outside the U.S. and Canada. This is partly because in most other countries the railways use lighter rolling stock; in some it is also due to traffic conditions or the need for economy in building the railways. Rail sections varying from 36 to 75 lb. per yard are common in South America. In Japan, 110-lb. rail, or heavier, is used on dense traffic lines, but there is much mileage of lighter rails in service.

Rail Fittings.—As rolling stock became heavier, railways found that under heavy traffic the rails tended to dig into the cross-ties, thus shortening the life of ties and making it difficult to maintain proper gauge and track alignment. To overcome this difficulty, tie plates are used between the base of the rail and the top of the tie. These plates (they may be up to 14 or 16 in. long on U.S. heavy traffic lines) distribute the load over more of the tie area. In some cases a resilient tie pad of rubber or a similar material is used between the tie plate and the tie.

The standard spike, with offset head, is still the most used fastening. It is driven through holes in the tie plates. In some cases railways have used special types of fastenings, including screw spikes and compression clips. These do an excellent job for critical locations, as on sharp curves or bridges, but they are considered too expensive for general use in the United States. Bolts or clips are used extensively in Europe.

Welded Rail.—One of the most important developments was the welding of rail into long lengths. This continuous welded rail increases travel comfort and saves maintenance. The rail is usually welded into lengths of up to a half-mile. In a few cases these lengths have, in turn, been welded together to produce rails several miles long without a break.

Welded rail was first tried in 1933 by the Delaware and Hudson railroad in the U.S. This line had laid 30-odd miles of continuous rail by 1939. It was not until the decade of the 1950s, however, that U.S. railways began to turn to welded rail in earnest. By 1960 about 1,000 mi. of long rails were being laid annually, and about 1% of all U.S. railway mileage consisted of welded rail. In the 1950s, the French railways alone laid over 3,000 mi. of long welded track and it was also being standardized in Britain. Japan and other countries also were adopting welded rail.

Controlling the temperature expansion of long welded rails proved not so difficult as was first thought. It was found that the problem can be minimized by extensive anchorage of the rails against the ties to prevent them from moving when the temperature changes, and by laying the rails when the ambient temperature is close to the mean temperature prevailing in the particular locality. In France and some other countries, beveled expansion joints, in

appearance somewhat like switch points, are sometimes provided at the ends of long welded rails.

4. Crossties (Sleepers).—Although timber is still the commonest tie material, both steel and concrete are also used. Steel ties are common in certain European countries, notably Switzerland, and they have also been adopted by a number of African and Asian systems. Concrete ties gained in popularity after initial stressing problems were overcome. Both prestressed and post-stressed types are in use, as well as concrete ties and concrete blocks joined by metal spacing bars. A combination of concrete ties and long welded rail is said to produce an especially solid form of track.

With concrete ties, the resilience of wood, is, of course, lost. To avoid excessive pounding of both the tie and rolling stock, some form of cushioning pad, of rubber or similar material, is always used between the tie plate and the concrete ties. Bolts or clips are used to fasten the rail to the tie.

Methods of treating wooden ties with preservative chemicals (usually creosote) were improved to a degree that the average life of crossties in the U.S. increased to more than 30 years. Nevertheless, the cost of wooden ties rose steadily, thus creating some interest in ties made of substitute materials. In the early 1960s several U.S. railways, notably the Atlantic Coast Line railroad and the Seaboard Air Line railroad, placed in service experimental sections of track laid with prestressed concrete ties.

5. Roadbed.—Early U.S. railways often were constructed as cheaply as possible. This meant that they usually followed the contour of the ground; earth cuts and fills, where required, were minimized. Railways built in this way often have steep grades and sharp curves, features that greatly increase operating costs and restrict train length and speed. With the advent of modern high-capacity earth-moving machinery (developed primarily for highway construction) railways were able in many cases to eliminate the old adverse grades and curves through line changes. Graders, bulldozers and similar equipment make it practicable to dig deeper cuts through hillsides and to make higher fills where necessary in order to smooth out the profile of the track, and to do this at a reasonable cost.

Modern equipment also helped railways improve their existing roadbeds, even where major changes were not required. For instance, a number of railways carried out ditching programs, in which the drainage ditches on each side of the right of way were deepened, thus improving drainage and increasing the stability of the roadbed. Where roadbed conditions are unstable, railways often find that it pays to remove the unstable material and replace it with filler material from another location. Stabilizing of the subgrade by injecting concrete grout under pressure is another widely used technique. In planning roadbed improvements, as well as in new construction, railways turned to modern soil engineering techniques (*see SOIL MECHANICS*).

The first step in building a new railway line, after the route has been surveyed and cleared of brush and trees, is to grade the right of way, much as is done in building a highway. Next, the ties are distributed and the rails laid and spiked. Then, ballast (usually crushed rock, slag or volcanic ash) is applied. Finally, the track is aligned in both the horizontal and vertical planes and the ballast is tamped or compacted around and under the ties.

In Canada, where much new railway mileage was built in the years following World War II, track-laying machines are often used. A track-laying machine, mounted on rail cars, feeds ties and rails ahead of the working crew, moving forward over the new track as soon as it is spiked down.

6. Track Maintenance.—Until after World War II, the system of section maintenance—descended from the early days of railways—remained standard in the U.S. and Canada. The typical section was only a few miles in length. It was under the supervision of a section foreman and a gang which might vary in size from 4 to 12 men. They had only a few hand tools. However, because of rapidly rising labour costs, the pressure to develop more economical track maintenance methods became intense.

With modern techniques, a small mechanized force of men can maintain a long stretch of track to high standards. Machines are available to do all the necessary track and maintenance jobs: re-

moving and inserting ties, tamping ballast, spiking rail, tightening joint-bar bolts and leveling and aligning the track. Mechanized forces also can renew rail, either in conventional bolted lengths or with continuous welded lengths; they use cranes to remove the old rail and lay the new. Gauging, spiking and bolt-tightening devices complete the installation.

Ballast-cleaning machines pick up old ballast, sift it, reject oversize or undersize stones, and replace it. Tamping machines consolidate ballast beneath the ties, thus improving running conditions. Scarifiers break up hard, compressed ballast. Complete sections of track—rails and crossties—may be prefabricated at a central shop and then laid on the site by mechanical means.

Rail grinding machines are used to even out irregularities that occur on the running surface of rails. For checking any irregularities in track alignment, other machines are capable of testing for gauge, curvature, etc., while in motion, the results being recorded on moving charts. So-called detector cars, equipped with electronic inspection apparatus, move over main-line tracks periodically to locate any internal flaws in the rails that might cause them to break under the stress of traffic.

Mechanization reduced the number of track and roadway maintenance workers in the U.S. by about one-half in 15 years following World War II. It constituted a major technological revolution. Improved and more automatic maintenance machines were constantly being developed, and U.S. railways were adopting new construction techniques that promised to reduce the amount of maintenance that the track structure requires. The trend to mechanization of track and roadway work was evident also in many other countries, but in most, mechanization was less advanced, largely because labour costs were not as high as in the U.S.

III. LOCOMOTIVES

Although some of the earliest railways used horses for motive power, it was only the development of practical locomotives that permitted railways to become efficient arteries of volume transportation.

Normally the term locomotive refers to a separate unit incorporating nothing more than the machinery to generate (or, in the case of an electric locomotive, to convert) power. However, motive power can also be incorporated in a vehicle equipped with passenger or baggage accommodations, or both. Broadly speaking, there are three sources of power for a locomotive: steam, oil and electricity. Steam was the earliest form of propulsion and was in universal use for over 100 years, but after World War II the popularity of the steam locomotive dwindled in favour of diesel and electric traction, which are more efficient.

The steam locomotive is a self-sufficient unit, carrying its own water supply for steam generation and either coal, oil or wood for heating the boiler. The diesel locomotive also carries its own fuel oil supply, but because of the characteristics of the diesel engine, direct drive to the wheels is not employed. Instead, mechanical, hydraulic or electric transmission is used; with the last, the diesel engine drives a generator to produce electric power and this, in turn, is fed to traction motors that propel the vehicle.

With electric traction the locomotive is not normally self-sufficient. As the locomotive moves along the track, electric current is picked up from either an overhead conductor wire or a third rail mounted alongside the running rails. The only self-sufficient examples are battery-driven electric locomotives and rail cars, which are not widely used. The only other category of motive power is the turbine locomotive—either the turbo-diesel or the gas turbine. Both use oil fuel and have electric, hydraulic or mechanical transmission.

A. STEAM LOCOMOTIVES

It was George Stephenson's "Rocket"—winner of the Liverpool and Manchester railway's competition of 1829—that ensured a place for the steam locomotive as a means of propulsion and the railway as a means of transport. The success of the "Rocket" was attributed to its multitube boiler and its more efficient system for exhausting the steam and creating a draft in the firebox, basic features that continued to be used in the steam locomotive. The

principal characteristics of the "Rocket" were a boiler pressure of 50 pounds per square inch (p.s.i.); cylinders $8 \times 16\frac{1}{2}$ in.; one pair of driving wheels, 4 ft. $8\frac{1}{2}$ in. in diameter; and a total weight of about 9,500 lb.

The number of coupled drive wheels soon increased. After the "Rocket," with its single pair of driving wheels, came the four-

coupled locomotive, followed by the six-coupled. The number of coupled wheels grew to a maximum of 14, a locomotive with this remarkable number being built in Russia. Additional wheels of smaller diameter are often provided ahead of and behind the coupled wheels. The pilot wheels ahead of the coupled wheels fulfill various functions, the principal one being to assist in guiding the coupled wheels around curves. The pilot wheels usually consist of two on a single axle or four on two axles. Those to the rear of the coupled wheels normally support the weight of the firebox, enabling it to be larger than if it had to be accommodated between the last pair of coupled wheels. (Common wheel arrangements, and methods of designating them, are shown in Table III.)

Steam locomotive driving wheels are of various diameters, usually larger on passenger locomotives and smaller on freight locomotives. In Europe the average is between 66 and 78 in. for express passenger engines and 54 and 66 in. for freight or mixed-traffic types. Typical locomotives built in the U.S. just before the end of the steam era had drivers ranging from 60 to 84 in. in diameter. At one time it was thought that locomotives with small coupled wheels could not be operated at high speeds, but this later was disproved; for example, 2-10-0's with 5-ft. diameter wheels have been run at 90 m.p.h.

Supplies of coal and water can be carried on the locomotive frame itself (in which case it is called a tank engine) or may be carried in a separate vehicle (the tender) attached to the locomotive; the latter arrangement allows far greater supplies of fuel to be carried. The average capacity of a tender of a European main-line locomotive is 10 tons of coal and 8,000 gal. of water. In Russia and on some African, Asian and Australian systems higher capacities are common. The tender for a typical large U.S. steam locomotive of the World War II period was carried on 14 wheels and had a capacity of 28 tons of coal and 25,000 gal. of water.

1. U.S. Locomotives.—In relatively short order, steam locomotives in the U.S. evolved to the general type that became known as the American Standard. It had a horizontal fire-tube boiler, a four-wheel pilot truck to steady and guide the front of the locomotive, and four coupled driving wheels. This 4-4-0 type was used in the U.S. for all kinds of services; it dominated U.S. railroading until well after the American Civil War period. In fact, many 4-4-0's were still in service by the early years of the 20th century.

Nevertheless, to meet the needs of heavy freight traffic, other

types of locomotives with more (and usually smaller) drive wheels were developed. Common were the Mogul (2-6-0), the Consolidation (2-8-0) and the Mikado (2-8-2). The Union Pacific used a three-cylinder 4-12-2, which had 12 coupled driving wheels. In the late years of steam locomotive development, still greater tractive effort was obtained by using two separate engine units under a common boiler. These articulated locomotives culminated in the Union Pacific's famous "Big Boy," said to be the largest steam locomotive ever built. Used in mountain freight service, "Big Boy" was an articulated 4-8-8-4 type which weighed nearly 600 tons. It could exert 135,375 lb. of tractive force and developed over 6,000 h.p. at 75 m.p.h.

2. Articulated Locomotives.—Articulated designs have also been produced in other countries. One of the best known is the Beyer-Garratt, in which there are two frames, each having its own driving wheels and cylinders, surmounted by water tanks. Separating the two chassis is a further frame carrying the boiler, cab and coal or fuel oil supplies. This type of locomotive is of particular value on tracks which permit only light axle loads, as the weight is spread over a considerable distance. Also, the Garratt can negotiate sharp curves. It is widely used in Africa.

Another form of articulation is the Mallet, in which there is a long rigid frame, below which are two sets of driving wheels each with its own set of cylinders. The rear driving wheels are frame mounted, but the leading ones are pivoted. The name Mallet is taken from the Swiss engineer, Anatole Mallet, who devised the layout for use with compound propulsion.

Simple-expansion steam locomotives can be equipped with two or more cylinders and, especially in Britain, three- and four-cylinder locomotives are common. For double expansion or compounding, more than two cylinders are mandatory. In this system, steam goes first to one or two small cylinders and then to two larger cylinders before being exhausted into the atmosphere; thus it is expanded or used twice, resulting in greater thermal efficiency. In Europe, compound locomotives were most popular in France, where for many years the majority of the designs were of this type.

3. Modern Types.—Typical of modern steam locomotives is the French railways 2-4-1 P class (4-8-2), a four-cylinder compound engine with 79½-in. drivers, a boiler pressure of 290 p.s.i. and tractive effort of 45,084 lb. The South African railways class 25 (4-8-4) has two cylinders, 60-in. driving wheels and develops 51,400 lb. of tractive effort. The Indian Government railways class WG (2-8-2) has 61½-in. driving wheels and develops 38,890 lb. of tractive effort. The British railways "West Country" class (4-6-2) has three cylinders, 74-in. drivers and can produce 27,720 lb. of tractive effort. Total weights of these engines, with tenders, range from 288,000 to 498,000 lb.

Typical of latter-day U.S. steam passenger locomotives were the Pacific (4-6-2) type and the Hudson or Baltic (4-6-4), which could haul heavy trains at high speeds. The Mountain (4-8-2) and Northern (4-8-4) types were logical further developments in passenger train power. The New York Central's Niagara 4-8-4 represented perhaps the highest state of development in passenger locomotives; this locomotive (also used in high-speed freight service) had a tractive force of 61,500 lb. and developed 4,850 h.p. at 65 m.p.h.

Various refinements gradually improved the reciprocating steam locomotive. Some of these included higher boiler pressures (up to 290 p.s.i. in France and up to 310 p.s.i. for some of the last U.S. locomotives), superheating, feed-water preheating, roller bearings and the use of poppet valves instead of the sliding piston valve. Nevertheless, the thermal efficiency of even the best modern steam locomotives seldom exceeds about 6%. Incomplete combustion, heat losses from the firebox, stack, boiler and cylinders, and other losses dissipate most of the energy of the fuel burned. In terms of modern technology, the reciprocating steam locomotive is obsolete. Yet it has its good points, not the least of which are its simplicity and ability to withstand abuse. See also STEAM.

B. ELECTRIC LOCOMOTIVES

The first challenge to the supremacy of steam came from the

electric locomotive. Although efforts to propel railway vehicles using batteries date back to 1835, the first successful application of electric traction was in 1879, when a locomotive designed by Werner von Siemens was operated at an exhibition in Berlin. In 1881 the first public electric railway commenced operation at Lichterfelde, near Berlin, while in 1883 the first part of Magnus Volk's electric railway at Brighton, Eng., was opened. Another early electric line was the City and South London railway between King William street and Stockwell. This was opened in 1890 and was the first electric underground railway. The initial applications of electric traction were for suburban or metropolitan railways such as those in Berlin, Budapest, Paris and London (see **ELECTRIC TRACTION**). In 1895 the B. & O. electrified a stretch of track in Baltimore to avoid smoke and noise problems in a tunnel, marking the first use of electrification by a steam railway in the U.S.

One of the first countries to use electric traction for main-line purposes was Italy, where a three-phase, 3,000-v. system was inaugurated in 1902. In the same year, some remarkable experiments were carried out on an experimental line near Berlin, where an electric train achieved a speed of 130.4 m.p.h.

By 1906, a number of electrified lines were operating all over Europe and a start had been made on major electrification schemes. Of these, the most extensive was in Switzerland, where large-scale electrification started at the end of World War I. Other countries that began extensive electrification in the 1920s were Sweden, Germany and Austria. All of these, together with Norway, made use of the same system: 15,000-v., 16 $\frac{2}{3}$ -cycle, single-phase A.C. In other countries, direct current was preferred, although Italy electrified a considerable mileage with 3,700-v., 16 $\frac{2}{3}$ -cycle, three-phase A.C. The use of the overhead conductor wire was almost universal, except for suburban lines and the Southern railway in Britain. By the end of the 1920s nearly every European country had at least a small percentage of electrified track. Electric traction was also introduced in Australia (1919), New Zealand (1923), India (1925), Indonesia (1925) and South Africa (1926).

Following the pioneer B. & O. tunnel electrification, a number of other terminals in the U.S. (such as the New York Central's Grand Central terminal in New York city) and difficult mountain segments of main lines were electrified. Some of these relatively small electrifications were later removed with the advent of the diesel-electric locomotive.

In the 1960s, the only major line-of-road electrifications in the U.S. were on the Pennsylvania railroad (about 671 route miles between New York and Washington, D.C., and between Philadelphia and Harrisburg, Pa.) and on the Milwaukee road in Montana, Idaho and Washington (about 660 mi.). There was also 106 mi. of electrified line on the New York, New Haven and Hartford railroad.

The suburban passenger services of several U.S. and Canadian railways were electrified, including the Canadian National at Montreal, the Long Island and the Erie-Lackawanna railways around New York city, and the Illinois Central at Chicago. Several South American countries have small mileages of electrified track, notably Brazil. About 11% of the route mileage of the Japanese National railways is electrified.

Following World War II, electrification was greatly extended in Europe in a comparatively few years, while there was also expansion in Africa, Asia and Australasia.

1. Advantages and Disadvantages.—Electric traction is generally accepted as the most economical and efficient means of operating a railway, providing that the traffic justifies the capital expenditure and that cheap electricity is available.

Being simply power-converting, rather than power-generating, devices, electric locomotives have several very real advantages. Since they draw on the resources of the central power plant, they can develop power greatly in excess of their nominal ratings to start a heavy train or surmount a steep grade. A typical modern electric locomotive rated at 4,000 h.p. has been observed to develop as much as 10,000 h.p. for a short period under these conditions.

Moreover, electric locomotives are quieter in operation than other types, they produce no smoke or fumes, they accelerate

rapidly, and they are completely predictable in performance. Electric locomotives have a high availability factor (that is, they require little time in the shop for maintenance) and, because of their relatively simple construction, the cost of maintaining them is low. It also appears that electric locomotives have a longer economic life than do diesel electrics.

The greatest drawback to electrified operation is the high capital investment and the maintenance expense of the fixed plant—the trolley wires and structures, power substations and associated equipment. A less important disadvantage is the lack of flexibility of electric motive power: it cannot operate where there are no trolley wires.

Electric operation is most suited to railway systems carrying very dense traffic; this is the basic reason why it made rapid headway in many European countries. In Japan, too, further electrification seemed inevitable as a means of more economically handling the extremely heavy traffic that characterizes the Japanese railways.

2. Types of Systems.—Electric traction systems can be broadly divided into those using alternating current (A.C.) and those using direct current (D.C.). With D.C., the most popular line voltages are 1,500 and 3,000, although there is a large mileage in southeast England of 600 v., and several systems in the 600–700 v. range around New York city. The disadvantages of D.C. are that expensive substations are required at frequent intervals and the overhead wire or third rail must be relatively large and heavy. Thus, a very high density of traffic is necessary to justify the cost of this form of electrification.

However, the low-voltage, series-wound D.C. motor is well suited to traction purposes, being simple to construct and easily controlled. Typical of modern locomotives for D.C. operation is the French railways 1,500-v. 9200 series, weighing 82 tons and developing 5,200 h.p. It was on a line equipped with the 1,500-v. D.C. system that, in March 1955, two different types of French locomotives achieved a speed of 205 m.p.h.

Single-phase A.C. at 16 $\frac{2}{3}$ cycles per second (c.p.s.) is also widely used by a number of European systems. With this system, substations do not need to be so numerous nor does the power transmission equipment need to be so substantial. Its application has been bound up with the lengthy development of the A.C. commutator motor. Initial A.C. electrification was on the three-phase system and the first practical application was on the Burgdorf-Thun railway in Switzerland in 1899, using a line voltage of 750. The first trial with a single-phase supply was on the Seebach-Wettingen line in Switzerland in 1907. The Bern-Lötschberg-Simplon, another Swiss system, was the first railway to be operated on single-phase, 16 $\frac{2}{3}$ -cycle A.C., at a line voltage of 15,000, throughout its length (1910–1913) and this type of power was subsequently adopted by the Swiss Federal railways.

In the United States, single-phase A.C. at 25 cycles was used on a number of the main-line electrifications. The Pennsylvania and New Haven systems are of this type.

Quite early in the development of electric traction the question of using alternating current at the industrial or commercial frequency (50 c.p.s. in Europe, 60 in the U.S.) was considered. Use of commercial-frequency A.C. means that current can be obtained from the commercial supply network, eliminating the need for the railways to generate and distribute their own power. The overhead contact wire can be much lighter, far fewer substations are necessary, and therefore lines with a lower density of traffic can be electrified on a profitable basis. Initial experiments with 50-cycle A.C. were carried out in Hungary in 1933, using a line voltage of 16,000. In the same year the German State railways decided to experiment on the Höllental branch with this form of electrification, using a line voltage of 20,000.

In 1945, Louis Armand, former president of French railways, set up a commission to study 50-cycle operation on the Höllental line. As a result, French railways pressed forward with the further development of 50-cycle electrification, converting a line between Aix-les-Bains and La Roche-sur-Foron for their first practical experiments. This was so successful that in 1952 it was decided to electrify a network of lines in northeast France using 25,000-v.,

50-cycle, single-phase A.C. Subsequently, a number of other countries adopted 50-cycle electrification, including Britain, Turkey, Portugal, Russia, India, the Belgian Congo, China, Japan and Argentina.

With the commercial-frequency A.C. system, there are three ways of taking power to the driving wheels: (1) employ a rotary converter or static rectifier to convert the A.C. supply to D.C. to drive D.C. traction motors; (2) use a phase converter to produce three-phase, variable-frequency current to drive A.C. motors; (3) make direct use of A.C. traction motors. The first method, using mercury-arc, germanium or silicon rectifiers, is the most popular.

The problem of international operation of electric locomotives in Europe was increased by the variety of electrification systems there. It was partially overcome by the construction of multi-voltage and multi-frequency locomotives. A similar problem exists in New York city, where the New Haven railroad operates into Grand Central terminal via the New York Central's 660-v., D.C. electrified system. The New Haven electric locomotives can operate either on 660-v. D.C. or 11,000-v., 25-cycle A.C. The New Haven also operates unique electric-diesel electrics. When in Grand Central terminal these locomotives operate from the 660-v. third rail; at all other times their traction motors are supplied from a standard diesel-electric engine-generator set carried on the locomotive.

Although electrification had made little headway in the U.S. up to mid-century, several factors were at work that showed promise of resulting in further electrification in the future. These included the demand for faster freight trains, the rising costs of diesel fuel, and a trend toward mergers that would tend to increase traffic density on the surviving lines. There was also the possibility of reducing fixed-plant costs through the use of the high-voltage, commercial-frequency system that has proved so successful in Europe and in Japan.

C. DIESEL-ELECTRIC LOCOMOTIVES

By the 1960s the diesel-electric locomotive had almost completely superseded the steam locomotive as the standard railway motive power in North America, and it was gaining rapidly in most other parts of the world. As the decade began, the Norfolk and Western railway, the last major U.S. system to continue steam operation, had completed its dieselization and was retiring its great steam locomotives, said by many to have been the most efficient steam motive power ever operated. In short, the railways of the U.S. in just 25 years, completely replaced the steam locomotive—which had been standard for 100 years—with the diesel electric. Actually, most of this change was accomplished in an even shorter period: as late as 1951 U.S. railways had more steam locomotives than diesel-electrics in service.

TABLE IV.—Designations of Wheel Arrangements of Diesel and Electric Locomotives

Symbol	Wheel Arrangement (front to back)	Description
A1A-A1A	○ ○ ○ — ○ ○ ○	Single-unit locomotive with two six-wheel trucks, each with centre idler axle.
B-B	○ ○ — ○ ○	Single-unit locomotive with two four-wheel trucks, all axles driven.
C-C	○ ○ ○ — ○ ○ ○	Single-unit locomotive with two six-wheel trucks, all axles driven.
2+(B-B)	○ ○ — ○ ○ + ○ ○ — ○ ○	Two-unit locomotive, each with two four-wheel trucks, all axles driven, units joined with articulated connection.
2-C+C-2	○ ○ ○ ○ ○ + ○ ○ ○ ○ ○	Electric locomotive with four-wheel leading and trailing (idler) trucks; six driven axles in two frames with articulated connection between frames.

What caused the diesel electric to supersede the faithful steam locomotive so rapidly? Briefly, the pressure of competition from other modes of transport, and the continuing rise in wage costs, forced the railways to improve their services and to adopt every possible measure to increase operating efficiency. Compared with the steam locomotive, the diesel electric (or simply, the diesel)

has a number of major advantages. For instance:

It can operate for long periods with relatively little down time for maintenance. This high availability makes it possible for diesels to operate through on a run 2,000 miles or more in length and then, after brief servicing, to start the return trip. Steam locomotives must be serviced after only a few hours in operation, and thus they are limited to relatively short runs.

The diesel uses less fuel than a steam locomotive (its thermal efficiency is about four times as great).

It can accelerate a train more rapidly and run at higher sustained speeds with less damage to the track structure.

These are the major points at which the diesel excels. It is also superior to the steam locomotive because of its smoother acceleration, greater cleanliness, standardized repair parts and operating flexibility (a number of diesel units can be combined and run by one man under multiple-unit [MU] control). With diesels, too, there is no problem of supplying large quantities of boiler feed water; there is no loss of power capability in cold weather; and there is less stand-by cost, since the locomotive can be completely shut down when not in use.

Because of advantages such as these, most U.S. railways found that diesel locomotives quickly paid for themselves, despite their relatively high initial cost. It is no exaggeration to say that without the diesel locomotive the U.S. railways could not have continued solvent under private operation.

1. Early Diesel Development.—The earliest patent for an oil-engine using the compression-ignition principle was granted in 1890 to a British pioneer, Akroyd Stuart. A small locomotive incorporating an engine of Stuart's design was built by Hornsby and Sons in 1896. The first patent for a compression-ignition engine was granted to the German engineer Rudolf Diesel in 1894, and the first engine to be built in accordance with his designs was completed in 1897 (see DIESEL ENGINE). The pioneer diesel-engine locomotive of any size was a 1,000-h.p. unit built by the Diesel-Klose-Sulzer company in 1912. It had a four-cylinder, two-stroke engine directly coupled to the driving wheels. This was followed in 1913 by the first diesel-electric rail car to operate in regular service, a Swedish design powered by a 75-h.p. engine coupled to a D.C. generator.

Gasoline-engine vehicles were in existence as early as the first compression-ignition engines. In 1891 two German firms jointly produced a small industrial locomotive with a 4-h.p. gasoline engine, and numerous other examples of gasoline-engine vehicles were produced in several countries following the turn of the century. Rail cars of various kinds, with gasoline engines, continued to be used up to the 1930s. In Europe, however, gasoline was too expensive to use for traction purposes, and its inflammability was a source of danger in the event of an accident.

The earliest ancestors of the modern diesel locomotive in the United States were the gasoline-driven rail cars used by the Union Pacific and other railways on branch-line passenger runs beginning early in the 20th century. The engines used in these cars were neither powerful nor reliable, nor were their mechanical transmissions suitable for such severe service. Next, gasoline-electric rail cars were developed, using larger engines and electric, rather than mechanical, transmissions. These proved more satisfactory, but they still did not fully solve the problem of branch-line passenger service.

After World War I, increased highway competition made the problem of money losing branch lines even more critical in the U.S., and led to renewed interest in gas-electric cars. The Electro-Motive company was formed in 1922 to build gas-electric cars, using engines supplied by the Winton Engine company and electrical equipment by General Electric company. Meanwhile, the American Locomotive company (Alco) had been experimenting with diesel engines, and in 1925 it produced the first commercially successful diesel-electric switching locomotive. This 300-h.p. 60-ton unit was sold to the Central railroad of New Jersey for service at its Bronx terminal in New York city. The locomotive went to work in Oct. 1925 and served continuously until its retirement in 1957 (this pioneer diesel unit is now preserved at the B. & O. transportation museum in Baltimore).

A little-remembered next step in North American diesel loco-

tive development was the delivery, in 1928, of "road" type locomotives to the Canadian National and New York Central railways. The C.N.R.'s locomotive, a 2,660-h.p., two-unit affair, was built by Canadian Locomotive company. Two smaller, single-unit locomotives, one freight, one passenger, were delivered to the New York Central by Alco and General Electric in the same year. These were not especially successful, but the C.N.R.'s two units were separated and continued in service, one until 1939 and the other until after World War II.

Diesel development continued in Europe during this period, also. There were rail car applications in several countries, as well as many examples of higher powered locomotives, notably in Germany and Italy. A Russian engineer, G. V. Lomonosoff, had been pressing the claims of diesel traction since 1910. The Russian government finally agreed to let him put his ideas into practice and in 1925, in conjunction with the German railways, a 1,200-h.p. diesel-electric locomotive was completed. This was followed by a similar unit equipped with mechanical transmission.

Much European development work in the 1920s centred on the transmission of power. Because of its characteristics, the diesel engine is very limited when equipped with direct drive because it cannot rapidly adapt to variable load requirements. Also, it cannot start from rest under load. Experiments were carried out with mechanical, hydraulic, pneumatic, compressed gas, compressed steam and electric transmissions. Gradually it was found that mechanical, hydraulic and electric transmissions were the most satisfactory. In 1928 a diesel-electric train was tested in Britain, and a diesel-hydraulic rail car was placed in service in Northern Ireland in 1933. However, it was in 1932 in Germany that the first really striking results with diesel traction were obtained. A two-car streamlined diesel-electric train, equipped with two 400-h.p. engines, commenced operation between Berlin and Hamburg. This train, the "Flederhamburger," was soon on a 77-m.p.h. average speed schedule that called for the regular attainment of 100 m.p.h. Other units were built and a network of fast services was introduced all over Germany. In the 1930s diesel rail cars and diesel-engine multi-car train sets were brought into use in most European countries.

A turning point in U.S. diesel development came in 1930, when Electro-Motive company and Winton Engine company were acquired by General Motors corporation. This merger led to the development of a lightweight, two-stroke-cycle diesel engine suitable for general railway application. This was the engine used in the "Pioneer Zephyr" of the Chicago, Burlington and Quincy railway. Delivered in April 1934, this was the first train in the U.S. to use diesel-electric power successfully in main-line service. Together with the Union Pacific's "M-10000," later renamed the "City of Salina," the "Pioneer Zephyr" also inaugurated the modern era of streamlined lightweight passenger trains. The "Pioneer Zephyr" remained in service for more than 25 years and then was preserved in the Museum of Science and Industry, Chicago.

The "Pioneer Zephyr," the "M-10000" (which used gasoline as fuel) and a few other early diesel-powered passenger trains were actually modernized versions of the old gas-electric cars. They were articulated trains in which a single truck supported the adjacent ends of adjoining cars. Cars could not be added or removed easily to meet traffic demands. In most cases the new trains were so popular that the traffic soon outgrew them, and eventually most of them had to be relegated to lighter-traffic runs.

Logically, the next step was to build a nonarticulated diesel locomotive that could be used to pull any train. In 1935 Electro-Motive division delivered one 1,800-h.p. unit to the B. & O. and two to the Santa Fe. The latter two units, operated as a single 3,600-h.p. locomotive, were used to begin the first high-speed passenger service between Chicago and Los Angeles, May 12, 1936. They covered the 2,226-mi. run, pulling the "Super Chief," in 39½ hr.

After 1935, the diesel began to play an increasingly important role in passenger train operations in the U.S., as well as in yard switching work, but it was not until 1939 that the first road freight diesel, a four-unit Electro-Motive demonstrator, was built. This 5,400-h.p. locomotive could be split and operated as two 2,700-h.p.

locomotives. The original demonstrator was eventually sold to the Southern railway. Meanwhile, the Santa Fe, in 1940, had become the first railway to operate diesel locomotives in regular freight service.

By the end of World War II the diesel locomotive had become a proven, standardized type of motive power, and it rapidly began to supersede the steam locomotive in North America. In 1943 there were nearly 40,000 steam locomotives and only 2,100 diesel units in service in the U.S. Less than 20 years later there were but a handful of steam locomotives in regular operation (mostly on short-line railways) and about 28,000 diesel-electric units. Because of its greater efficiency, this smaller number of units proved fully capable of performing as much or more transportation work than the larger steam locomotive fleet it replaced.

After World War II, the use of diesel traction greatly increased also in Europe, Africa, Asia and Australasia. Practically every major system in these areas used the diesel engine in some form, and there were some systems—especially in Africa—that became completely dieselized.

2. Elements of the Diesel Locomotive.—Although the diesel engine has been vastly improved in power and performance, the basic principles remain the same: drawing air into the cylinder, compressing it so that its temperature is raised and then injecting a small quantity of oil into the cylinder. The oil ignites without a spark because of the high temperature. The diesel engine may operate on the two-stroke or four-stroke cycle and may have cylinders arranged in line, in V formation, horizontally opposed or in vertical formation. Rated operating speeds are from 350 to 2,000 r.p.m. and rated output may be from 10 to 2,400 h.p.

In the United States, early road units, and most yard switchers, use diesels ranging from 600 to 1,200 h.p. Road units now commonly have 1,800-, 2,000-, or 2,400-h.p. engines. Most builders use V-type engines, although the in-line type is used on smaller locomotives (up to 1,200 h.p.).

Electric transmission is the most popular, and is nearly universal in North America. With electric transmission, the diesel engine is directly connected to a main generator that converts the mechanical energy produced by the engine into electrical energy. Through the appropriate control equipment, this in turn is used to drive the traction motors. The traction electrical system operates at a nominal 600 v., but there is great variation in the voltage under operating conditions. The traction motors are of the series-wound type, each geared to the axle it drives. Most locomotives have a traction motor on each axle, although some passenger locomotives or units designed for light branch-line service may have six-wheel trucks with the centre axle an idler.

Hydraulic transmission employs the principle of a centrifugal pump or impeller driving a turbine in a chamber filled with oil or a similar fluid. The pump, which is driven by the diesel engine, converts the engine power to kinetic energy in the oil impinging on the turbine blades. The faster the blades move, the less the relative impinging speed of the oil and the faster the locomotive moves.

Mechanical transmission is the simplest type and is mainly employed in the lower power range. Basically it is a clutch and gear-box similar to those used in automobiles. A hydraulic coupling, in some cases, is used in place of a friction clutch.

3. Types of Diesel Motive Power.—There are four broad classes of equipment using diesel prime movers:

The light rail car or rail bus (up to 180 h.p.) usually is four-wheeled and employs mechanical transmission; it often is powered by a standard motorbus engine or a horizontal or pancake engine. The vehicle may haul a light trailer car.

The rail car in the low horsepower range (up to 1,000 h.p.) usually is equipped with mechanical transmission; higher powered versions may have hydraulic or electric transmission. Nearly all rail cars are capable of hauling trailer vehicles, while the most powerful types are designed essentially for hauling additional vehicles, although they also have passenger or baggage space.

Train sets (500 to 2,000 h.p.) are formations of more than one vehicle, usually designed to be worked from a single set of controls. They include one or more powered vehicles in their formation and usually have hydraulic or electric transmission.

Locomotives (10 to 3,300 h.p.) may have mechanical, hydraulic or electric transmission, depending on power output and purpose. They

frequently are designed to work in MU formations. In the lower power range (to 600 h.p.) the usual duties are switching and light freight traffic. Medium-power locomotives (600-1,200 h.p.) may be used for freight haulage, passenger work or heavy switching purposes. Locomotives over 1,200 h.p. are normally required for main-line duties in Europe and North America. The 1,500-2,000 h.p. range is the most popular class for express train haulage, and for freight service in North America.

4. Diesel Operations in the U.S.—In North America, diesel locomotives are built in three distinct types designed for switching, freight and passenger service. Freight and passenger types are very similar in appearance, but passenger units are usually geared to a higher top speed and are equipped with an automatic steam boiler for train heating.

Road locomotives may be of either the streamlined or cab type, an outgrowth of the early streamlined articulated train designs,

or of the purely functional hood type. In the former the body conforms closely to the cross-sectional dimensions of modern passenger cars. In hood units the covering for the engine, generator and other components is smaller and is not streamlined. Yard engines are always of the hood type in the U.S. and Canada (with the exception of a few early box cab yard switchers).

The so-called road switcher or general-purpose diesel has become almost standard in the U.S. and Canada. This hood-type unit is usually geared for medium top speeds and has an offset cab located between a short hood (which may contain a steam generator) and a longer hood covering the diesel engine, generator and control equipment. The road switcher can be used in either passenger or freight service interchangeably, and it can also be assigned to yard switching service as needed. Because of this versatility, the number of locomotives required may often be substantially re-

duced when road switchers are used.

5. Operating Methods.—It became almost universal practice in North America to equip diesels for MU control. This permits setting up a "building block" system in which two or more units can be combined and operated as a single locomotive from one control cab. This can be done on short notice to cope with fluctuations in traffic, for example, or to obtain extra power for a mountain grade. The electrical systems of the different builders' locomotives are sufficiently standardized so that it is possible to operate units of mixed makes together in a locomotive "consist."

In the early days of dieselization, railways tended to emulate the operating methods they had used with steam locomotives, but to take advantage of the diesel's special characteristics they soon found it necessary to change their techniques, and often their physical facilities. For one thing, the diesel closed many division-point roundhouses, since it could run across a whole continent, if necessary, without requiring any maintenance attention. Moreover, many railways found it necessary to pay increased attention to the scheduling of motive power operations. Rather than having locomotives assigned to a maintenance terminal on a first-in, first-out basis, some roads found it desirable to operate as many units as possible on definite cycles. Such a cycle may take a locomotive to all parts of the line, hauling a succession of different regular trains, before it returns to the maintenance point after perhaps 15 days on the road.

D. SPECIAL LOCOMOTIVE TYPES

Although the diesel locomotive with electric drive is the present standard type in North America and over much of the rest of the world, railways are constantly experimenting with other types of locomotives. For example, on several occasions experiments have been made to adapt the steam turbine for rail traction purposes. One of the first examples was built in Sweden in 1921. Other prototypes followed in Europe and there were also experimental turbine-electric locomotives, none of which met with success.

The first gas-turbine locomotive was developed in Switzerland and completed in 1941. Another Swiss-built gas-turbine locomotive developing 2,500 h.p. was supplied to British railways in 1949. The first British-built gas-turbine locomotive developed 3,500 h.p. and was completed in 1951 (it was later converted to 25,000-v., 50-cycle A.C. operation).

Shortly after World War II the Union Pacific railroad (U.P.) acquired a total of 25 gas-turbine electric locomotives of 4,500 h.p. each to be used on main-line heavy-duty freight service between Omaha, Neb., and Ogden, Utah. Although the gas-turbine is not as efficient as the diesel engine, the U.P. found that the turbine locomotives can develop high sustained speeds with heavy trains, and that they cost less to maintain than diesel-electric locomotives of comparable power. The original 25 units were subsequently supplemented by thirty 8,500-h.p. units.

Union Pacific also experimented with a coal-fired, gas-turbine electric locomotive. Work on a coal-burning gas-turbine locomotive began in the U.S. after World War II, and research and testing solved many problems inherent in using coal in a gas turbine. The coal-burning turbine was considered to have significant possibilities for railways which, like the U.P., serve areas rich in coal.

Also employing a turbine is the turbo-diesel or free-piston gasifier locomotive. In this design the turbine is driven by power gas from a free-piston diesel compressor. Pioneer work with this type of engine for rail traction purposes commenced in Sweden in 1933.

In 1955 another Swedish locomotive was produced, much larger than the original example. It had a power-gas producer that worked on a two-stroke-cycle diesel principle (the power gas is exhaust gas leaving the producer under high pressure at a temperature of 900° F.). The locomotive was driven, via a reduction gear, by the turbine, fed by the power gas. It developed an output of 1,300 h.p. and used 20% less fuel than the equivalent diesel-hydraulic or diesel-electric locomotive.

E. SELF-PROPELLED RAIL CARS

Although the gas-electric and gas-mechanical cars of the 1920s

and earlier evolved into the diesel-electric locomotive, they were not too successful in their intended role. In the U.S. especially, there was still a need for a self-propelled rail car that could be used on light-traffic lines.

In 1949 the Budd company introduced a modern self-propelled coach that it called the rail diesel car (R.D.C.). The 85-ft. stainless steel car was powered by a pair of 300 h.p., 6-cylinder, in-line diesels, each of which drove one axle through a torque converter. The engines were mounted under the floor, leaving almost the entire car body available as revenue space. The car had a control compartment at each end, could be operated in MU trains with other R.D.C.'s, and was air-conditioned.

The R.D.C. found favour with many railways in the U.S. and other countries. The Commonwealth Government railways in Australia began using these self-propelled diesel cars on long-distance runs.

Self-propelled cars have been widely used for many years for electrified commuter service serving larger cities, as well as on local subway and rapid-transit systems. Modern MU cars, as they are called, can accelerate and decelerate rapidly because of their lightweight construction and improved motors and control equipment. (See ELECTRIC TRACTION.)

In its Chicago-area commuter operations, the Chicago and North Western railway began using nonpowered cars equipped with MU control equipment, and a control cab, in conjunction with standard diesel-electric locomotives. By having one of these control cars at the rear of a train, it is possible to operate the train in either direction at normal speed, without turning the locomotive or cars at either end of a run.

IV. RAILWAY CARS

The ancestors of modern freight and passenger cars were the wagons and stage coaches of the early 19th century. Some of the earliest railway cars were, indeed, merely road vehicles fitted with flanged wheels.

After the first crude beginnings, railway car design took diverging courses in North America and Europe, partly because of differing economic conditions on the two continents and partly because of differing technological developments. Early railway cars on both continents were largely of two-axle design, but passenger car builders soon began building cars with three and then with four axles, the latter arranged in two four-wheel swivel trucks or bogies. Swivel trucks produce smoother riding qualities and allow the weight of heavy cars to be distributed over more axles—an important consideration, especially on some of the early, lightly built rail lines.

In North America, the two-truck design soon became the standard for freight as well as passenger cars. Over the years, American freight cars have become much larger than their European counterparts. A typical modern American boxcar is about 50½ ft. long, weighs 53,000 lb. empty, and has a capacity of 100,000 lb. of lading and a cubic capacity of 4,860 cu.ft.

To a remarkable extent, the characteristics of rolling stock reflect the background of the early railway builders in each country. Thus, the cars used in Africa and most Asian countries reflect European origins; South American equipment favours North American or European practice, depending on who built the first lines.

In Japan most freight cars are of the four-wheel type, but in Australia eight-wheel truck-type cars are more common. After World War II, there was a trend in European countries toward larger, eight-wheeled freight cars, but European railways are often handicapped by close clearances and sharp curves on factory loading tracks.

A. FREIGHT CARS

Three basic types of freight cars have developed: the open-top car, the boxcar and the flatcar. Apart from these examples, many additional designs have been introduced to suit particular types of freight. In Europe, the freight vehicle usually runs on four wheels. Capacity varies: British cars are the smallest, having an average capacity of 12 long tons, although vehicles taking 16, 20

and 24½ long tons are in use. On the continent capacities vary from 16 metric tons to 30 metric tons. In Russia, however, much larger two-truck vehicles are generally employed, having capacities of up to 90 metric tons. Two-truck cars having a capacity of up to 30 or 40 long tons are also used to a great extent in Africa, Australia and most Asian countries.

After World War II a number of new freight car designs evolved in Europe. These included double-deck vehicles for transporting automobiles; open cars with sliding roofs; pressurized tank cars for the transport of dry solids in bulk; boxcars with wide side doors for the easy movement of loads packed on pallets; and hydraulically operated tipping cars.

European railways also made great strides in the use of demountable containers carried on flatcars. These were first introduced in the 1920s to enable the railways to offer a door-to-door service and there came to be many examples in service for the transport of all kinds of merchandise from liquids to highly perishable commodities such as frozen food.

Of the approximately 2,500,000 freight cars operating on U.S., Canadian and Mexican railways, about 800,000 are boxcars—the standard house car with closed sides, a roof, and sliding doors on each side. Cars of 40- and 50-ft. lengths are common, but the trend is to larger units. American railways use an equally large number of open-top cars—so-called gondola and hopper cars, the latter having hoppers with doors for unloading through the bottom. Other common American freight car types include flatcars, tank cars and refrigerator and livestock cars.

Many thousands of cars are equipped with special internal fittings designed to accommodate specific products without the need for dunnage (*i.e.*, bracing or blocking of the load). Typical of these are the automobile parts cars, which are often designed to carry a certain automobile component, such as bodies, frames or engines, of just a single manufacturer. The internal loading equipment in these cars must be changed whenever the automobile manufacturer changes the design of his product.

Among other special types of boxcars are those with "long-travel" cushioned draft gear to prevent damage to fragile commodities; heated cars to protect commodities such as potatoes during winter; extra-long flatcars with two- or three-deck automobile racks, and so on.

During the 1960s, still other types of specialized freight cars were becoming more and more important. Especially notable was the growing use of piggyback cars designed for efficient loading and hauling of highway trailers. Other new types included underslung flatcars for carrying high loads, 100-ton "tank type" covered hoppers for dry bulk commodities and 10,000-cu.ft. boxcars for light but bulky automobile parts.

For the railways, the growing variety of specialized freight cars complicated the problem of keeping all shippers supplied with cars of the proper types. On the other hand, specialized cars usually ran more miles and earned more revenue than standard cars, and thus were a worthwhile investment. To supply special freight cars more efficiently, the private car companies played an increasing role. These companies buy the equipment and either operate it or lease it to shippers and often to the railroads themselves, a practice long followed in the U.S. with tank and refrigerator cars.

B. PASSENGER CARS

Cars with two four-wheel trucks were used in the United States almost from the beginning, but the two-truck coach was not introduced into Britain until 1874 and on the European continent until 1880. At about the same time the flexible gangway or corridor connection was adopted for main-line cars, enabling passengers to have access to any part of a moving train. Early American cars had open platforms at each end; it was not until around 1900 that closed-vestibule cars came into general use.

Sleeping cars were operated in the U.S. as early as 1837, and the first Pullman sleeper was placed in service in 1859; sleeping cars were introduced in Britain in 1879.

In Europe there was a gradual trend toward longer and lighter passenger vehicles. The standard British coach measures 67 ft. in length, while continental designs are up to 86 ft. 6 in. long.

The introduction of steel, first for coach frames and later for frames and bodies, added to the weight of vehicles. An all-steel continental coach might weigh up to 45 metric tons, or 55 metric tons for a sleeping car. However, it was found possible to reduce these weights without loss of strength by using lightweight steels, stainless steels and light alloys. For example a modern lightweight steel coach of the Swiss Federal railways is 73 ft. long, seats 80 passengers and has a tare weight of only 26 metric tons. In contrast, typical U.S. passenger cars weigh from about 60 to 80 short tons, or even more.

Experiments have been carried out with ultra-lightweight trains. The Spanish railways operate a number of lightweight sets, called Talgo trains, consisting of several short coach units, each resting at one end on a single axle. At the other end the weight is carried on a pivot which forms part of the next vehicle, and the leading coach is supported on the diesel locomotive. The train is thus made up of a series of jointed units and, having a very low centre of gravity, it can traverse curves at high speed.

The interior accommodations of passenger cars vary widely. In Europe the six- or eight-seat compartment with the corridor along one side of the coach is still favoured, although the use of coaches with a centre aisle has increased, particularly for suburban service. Reclining coach seats were adopted by a number of systems for long journeys.

United States passenger cars use the centre-aisle arrangement almost exclusively, except for some sleeping cars. Besides the coach, with its two rows of seats, the modern U.S. passenger train may include several types of sleeping cars for overnight travel, a dining car and a lounge or observation car. In addition, "head-end" cars—for mail, express and baggage—are operated in most U.S. and Canadian passenger trains.

A typical modern sleeping car has six bedrooms (each with two beds) in the centre of the car, with six roomettes (each with a single bed) at each end. Thus the total capacity of the car is about 24 persons. This relatively low capacity produces low revenue, making necessary rather high fares to cover the cost of operating the car. The high fares, in turn, discourage patronage in competition with the much faster airlines. This is the basic problem of sleeping-car service under modern conditions.

As one answer to this problem, the Budd company in the U.S. developed the "slumbercoach," a sleeping car similar to the roomette but with smaller rooms. It has 8 small double rooms and 24 single rooms. The total capacity of 40 makes possible rates only slightly above the standard coach fare. In use on a few lines in the U.S., slumbercoaches proved highly successful.

The dome car, developed in the U.S. after World War II, enables passengers to ride under a raised, glassed-in roof section from which they have a wide-range view of the countryside. Below the dome section may be sleeping rooms, a lounge section or coach seats. Although costly to build and operate, dome cars without doubt helped attract patronage. They became widely used on railways having scenic routes in the western U.S. and Canada. The same type of service was adopted in other countries as well, notably in France and Italy.

With growing industrialization many countries began building their own rolling stock, whereas previously they had obtained their cars from European or American builders. Many of the cars in service have been designed to suit climatic and other special conditions of the countries in which they operate. Narrow-gauge railways also impose restrictions as to weight and size. Even so, a 3-ft. 6-in. gauge coach of the South African railways, for example, may be up to 63 ft. 5 in. long and weigh up to 43½ long tons. In Australia the trend has been to longer coaches, many of which follow the American pattern in design and appearance.

C. STANDARDIZATION OF RUNNING GEAR

Although U.S. and Canadian railways build many different types of cars to suit their own needs or whims, most of the cars may operate interchangeably among railways. Through the work of the mechanical division of the Association of American railroads (and its predecessors) the elements of the running gear—wheels, trucks, draft gear, couplers and brakes—have been standardized. Not

only does this permit any car to operate over almost any railway on the North American continent, but it also allows any railway to repair or maintain any car it is using, regardless of who owns the car.

This mechanical standardization was an important factor in the growth of the American railway industry, yet it does impose some problems. Any improved type of coupler or brake, for example, must be compatible with existing older equipment if it is to be used on cars operated in interchange service. However, despite this limitation, mechanical progress has been steady. Roller bearings almost entirely replaced the traditional plain journal bearings on passenger cars and locomotives, and came into increasing use on freight cars. Several improved types of automatic couplers were adopted; an improved freight air brake, the type AB, became universal, and wheels were constantly improved. Truck or bogie spring systems were made more effective against vertical shocks and oscillations in moving cars, and the draft gear used in freight cars was refined to provide more cushioning against longitudinal jolts.

As a result of these changes, the mechanical standards of freight cars approached more and more those of passenger cars. This was a necessity, because longer trains were being operated at higher speeds, and it became even more urgently necessary to prevent damage to merchandise in transit.

1. Couplers.—European couplers originally consisted of nothing more than chains linking the vehicles, with solid buffers to help absorb the shock when one vehicle came in contact with another. Later, spring buffers were introduced, along with screw couplings that permit two vehicles to be brought together so that buffer faces are just touching; this helps to ensure smooth starting and stopping.

During their first half-century, U.S. railways used a crude link-and-pin coupler that was extremely dangerous to employees who had to couple cars. Beginning in 1882, American railways began to convert to the knuckle-type automatic coupler. This basic design, built heavier for today's larger cars and much improved in detail, is still the North American standard. Knuckle couplers are also used in many other countries, notably Japan, Russia and Australia. In fact, the majority of non-European railways use automatic couplers of one pattern or another.

In Britain, automatic centre couplings were tried out on the Great Northern railway in 1898. Later, automatic couplings were used on the main-line passenger coaches of the London and North Eastern and the Southern railways. In 1948 British railways adopted this type of coupler for all their main-line coaches, and experiments later began on an automatic coupler for freight cars.

Multiple-connection automatic couplings have been adopted by a number of railways, principally for diesel rail-car trains or MU electric trains. This type of coupling incorporates connections for the continuous brakes, heating and electrical controls, as well as joining the vehicles together.

Instead of buffers, U.S. cars have draft gear, directly behind and attached to the couplers, which may employ spring, friction, rubber or hydraulic elements to help absorb coupling and operating jolts. The standard draft gear is mounted in a pocket 24- or 36-in. long, but a number of long-travel draft gears and cushioned centre sills have been developed to give greater protection to fragile commodities.

2. Brakes.—Two continuous braking systems are in general use—the vacuum brake and the compressed-air brake. Of the two, the more popular is the air brake, patented in 1869 by George Westinghouse and made compulsory in the U.S. by the Railroad Safety Appliance act of 1893. The vacuum brake is used principally in Britain, where continuous brakes have been compulsory on passenger vehicles since 1889. With either system, every vehicle is connected by a brake pipe; therefore, application of the brake on the locomotive applies brakes throughout the train.

Although virtually all passenger rolling stock throughout the world is equipped with continuous brakes, this is not the case with freight cars. The majority of British freight cars, for example, do not have continuous brakes, although steps have been taken to remedy this situation. In other countries the bulk of the

freight stock is fitted with continuous brakes.

The brake itself takes the form of a single or double shoe which presses against the wheel tread. The disk brake also has been widely used on U.S. and Canadian passenger trains (*see also BRAKE*).

3. Dual-Gauge Vehicles.—Vehicles capable of running on more than one gauge are in use in Europe. The Spanish Transfesa company operates freight cars that can be used on the 5-ft. 6-in. broad gauge of Spain and on the standard 4-ft. 8½-in. gauge of other European countries. Special apparatus at frontier yards enables wheel sets of one gauge to be exchanged quickly for those of the other. Similar arrangements, on a larger scale, are to be found at certain Russian frontier stations, so that 5-ft. gauge Russian passenger coaches can receive standard-gauge trucks and operate into east and west European countries.

In some countries special cars are used to carry cars of a different gauge in piggyback fashion. In Australia, for example, complete trains of specially adapted flatcars are in use to carry, in turn, entire trains of a narrower gauge, thus obviating the need for transshipment of freight.

V. CAR AND LOCOMOTIVE MAINTENANCE

The design, construction and maintenance of rolling stock is a responsibility of a railway's mechanical department. In steam locomotive days, some of the larger railways (both in the U.S. and elsewhere) built their own locomotives, as well as many of their own cars. However, U.S. railways did not build new diesel locomotives, although there was a trend toward building cars in railway shops rather than having them built by the commercial car manufacturers.

In terms of money spent for wages, materials and the operation of shops, rolling stock maintenance is a vast operation. In normal years U.S. railways, for example, spend about 18% of their income for this purpose.

Railway shops perform all the operations and contain much of the machinery common to a heavy manufacturing industry. Moreover, railway shop production was being organized more and more around assembly-line techniques, just as in other industries.

1. Locomotive Shops.—In contrast to the steam locomotive back shops that railways formerly required on each operating division, the dieselized railway usually needs only one heavy repair shop. Here the locomotives are more or less completely dismantled and their major components—engines, electrical equipment, running gear—are either completely overhauled or renewed. Under normal conditions, a diesel locomotive is given heavy repairs or rebuilding only after a period of perhaps five to seven years. Between these major overhauls, a locomotive receives maintenance attention usually on the basis of mileage; that is, certain routine maintenance work is performed at specified mileage intervals (in the U.S., certain inspection and maintenance work is prescribed by the Interstate Commerce commission).

In addition, of course, locomotives also are given certain routine inspections at the end of each run. Although many railways still use converted roundhouses for much diesel maintenance, others have found that specially built diesel shops are more efficient.

2. Car Shops.—Freight car maintenance may be classified as running repairs, intermediate repairs and heavy repairs or rebuilding (the exact definition of each varies among railways). As trains enter terminal yards they are inspected for running gear or other defects. Any cars requiring attention are switched out of the train and sent to the "rip track," a shop equipped to do light repair work such as wheel changing, air-brake repairs and minor repairs to the car bodies.

If a car has been severely damaged, it may be sent to a heavy repair shop. Often, railroads rebuild an entire series of cars. This is most likely to occur after the cars have seen 15 or 20 years of service. The rebuilt cars may be equipped with entirely new bodies and emerge from the assembly-line car shop the virtual equivalent of new cars.

VI. BRIDGES, BUILDINGS AND TUNNELS

The fixed plant of a railway consists of much more than just the

track itself. In the U.S. alone, about 4,000 mi. of line are on bridges. In mountainous country, tunnels must be built to avoid excessive grades or excessively roundabout routes. Where mountain railways are not in tunnels they must often be protected by snow sheds against drifting and avalanches. In addition, railway engineering departments are concerned with constructing and maintaining thousands of different buildings ranging from small watchman's shanties to huge passenger terminals.

1. Bridges.—The designer of a railway bridge faces some challenging problems. He must allow for the forces that result from the concentrated impact as a train moves onto the bridge, the pounding of wheels, the sideway of the train, the drag or push effect as a train is braked or started on the bridge. These factors mean that a railway or rail-highway bridge must be designed more stringently than a highway bridge. The heavier construction of a railway bridge designed for main-line traffic, as compared with a highway bridge of similar length, is usually quite evident even to a casual observer.

As trains and locomotives became heavier, bridges had to be strengthened accordingly. In the past, newer, heavier steam locomotives usually caused the need for stronger bridges, but modern diesel-electric locomotives are less damaging to bridges than large steam locomotives. However, as freight loads became heavier and train speeds higher, railways still had to design and build their bridges to high standards.

Besides the need to strengthen bridges, there was another major objective in much modern railway bridge construction: reducing maintenance costs. This became evident in the widespread trend toward replacing timber trestles with concrete slab structures or with concrete or steel-pipe culverts. Prestressed concrete slab bridges came into use on an increasing scale. All-welded steel bridges, although remaining relatively rare on railways, became more common, as did the use of high-strength bolts rather than rivets for field assembly of bridge spans.

Under the spur of rising labour costs, U.S. railways sought ways to mechanize the maintenance of bridges and other structures. Typical of solutions to the problem were the bridge sprayer machines used to apply protective coatings, as well as special types of derrick equipment for replacing bridge ties and stringers. (See also BRIDGES.)

2. Buildings.—Railway buildings in the 20th century became fewer and more functional. The newer types of motive power, for instance, required only a few maintenance shops. Car shops, too, were being consolidated into fewer but usually more modern structures. In North America, the declining importance of passenger traffic resulted in the elimination of many passenger stations, and some local freight stations were removed, too, since with paved highways almost everywhere, it became more economical to concentrate freight terminal operations at a few large stations.

Only a few really modern passenger stations have ever been built in the U.S. One is the Los Angeles Union Passenger terminal; one of the latest is the New Orleans Union Passenger terminal, completed in 1954. Grand Central terminal in New York city, completed in 1913, is perhaps the best-known railway station in the world: approximately 150,000 passengers use it daily. In contrast, however, approximately 580,000 use the Tokyo station of the Japanese National railways daily.

Europe, however, has a number of large, modern passenger stations. One of the most striking is Rome Termini, the construction of which started in 1938, although it was not completed until 1951. Of prewar construction is the Central station, Milan, one of the largest in Europe. Opened in 1931, it has 22 platforms, of which 18 are 1,051 ft. long.

3. Tunnels.—Although it is a highly expensive form of construction, tunneling provides the most economical means for railways to traverse mountainous terrain and to gain access to the heart of a crowded city. However, railway tunnels confront the construction engineer with some unique problems, particularly in matters of ventilation on nonelectrified lines.

Some examples of famous tunnels and methods of construction may be found in the articles TUNNEL and SUBWAY (UNDERGROUND RAILWAY).

VII. COMMUNICATIONS AND SIGNALING

A. COMMUNICATIONS

Modern railways have operating and service problems as complex as those of a major manufacturing concern—in some respects even more so. The railway's plant and its operations may be spread out over thousands of miles of line serving hundreds of communities. Quick communication between stations is usually essential in the operation of trains. It is also required in order to give service information to the public and to carry on the vast amount of routine correspondence and accounting data that a railway enterprise generates.

1. Telegraph and Telephone.—Railways were among the first to adopt the electric telegraph and the telephone. The railway telegraph dates back to 1837, when it was tried on the London and Birmingham line. In the U.S., the telegraph was first used for dispatching trains in 1851; the telephone was first tested in 1877.

Modern railways are among the larger operators of electrical and electronic communications facilities. For example, the dial telephone network of the S.P. system covers the entire western area of the U.S. It allows personnel anywhere on the railway and its affiliates to dial direct to offices anywhere on the 14,000-mi. rail system serving 12 states. Other railways have similarly extensive telephone systems.

The Morse telegraph, originally used in North America for all railway business messages as well as train dispatching, eventually was relegated to use only on some secondary and branch lines, and train dispatching was done almost entirely by telephone, or by centralized traffic control signaling.

For message communication other than that involved in dispatching of trains, most U.S. railways came to rely heavily on the printing telegraph (Teletype) as well as the telephone. Many railways installed teleprinter networks to connect all stations, engine houses, yard offices and general offices.

The teleprinter is used for many purposes beyond the exchange of routine messages. One of the more noteworthy developments is the transmission of the complete train "consist" (or list of cars in the train) by teleprinter from the origination point of a train to the next terminal on its route. By having the exact train consist, the destination terminal can plan switching operations well in advance of a train's arrival.

Simultaneously, the same train consist list may be transmitted to the railway's general headquarters, where it can be used to inform customers of the whereabouts of their shipments. The consist can also go to the car records office, which records the movements of individual cars, and to the accounting department.

More and more, railways in the 1960s moved toward the concept of integrated data processing, which requires a data-processing centre usually located at company headquarters. Operations and accounting data of many types may be fed into this centre direct from outlying points on the railway. Often, one or more large electronic computers may be included in the complement of business machines.

Central data processing requires a large number of communications circuits. The capacity of a single pair of telegraph lines may be increased many times by superimposing on it a number of electronic "carrier" circuits, each operating in a different frequency range. But modern demands for circuits in some cases even exceeded the capacity available through carrier equipment. Thus, some railways turned to broad-band radio beams (microwave) to supply the many channels needed for direct telephone dialing systems and teleprinter and data processing circuits.

2. Radio.—In 1959 the Pacific Great Eastern railway, between Vancouver and Dawson Creek-Fort St. John, B.C., became the first railway to use microwave radio for all line-side communications, doing away almost entirely with line wires. Other major North American carriers, notably the Santa Fe, S.P. and U.P., also installed extensive microwave systems. Microwave has the additional advantage of minimizing communication failures in areas subject to heavy sleet and snowfalls, which might bring down conventional open-line wires.

American railways also began to use very high-frequency (VHF)

radio on a large scale after World War II. In freight operations VHF permits communication between the locomotive and caboose of a long train, between two trains, and between the train dispatcher and wayside stations and trains.

In terminals, radio greatly speeds yard switching work, because it allows the yardmaster to keep in close touch with the yard engines. Through VHF radio, too, widely separated elements of mechanized track maintenance crews can maintain contact with each other and with oncoming trains. Supervisory personnel use radio in their automobiles to keep in touch with activities under their jurisdiction.

To some extent, train radio took over some of the communication functions formerly reserved for the locomotive whistle. Enginemen commonly use standard combinations of long and short whistle sounds to communicate with the rest of the train crew and with wayside stations. On U.S. passenger trains, an intra-train air whistle system allows the conductor or trainmen to signal the engineman.

B. SIGNALS

Railway signals are a form of communication designed to inform the train crew (in particular, the engine crew) of track conditions ahead and to instruct it in the operation of the train.

The earliest form of signaling consisted of a lamp by night or a flag during daylight. The first movable signal was a revolving board, introduced in the 1830s and followed in 1841 with the semaphore signal, which provided "stop," "proceed with caution" and "all clear" indications. Among the widely used early types of signals in the United States was the highball signal, consisting of a large ball, hoisted to the top of a pole, to inform the engineman that the train might proceed. The first attempts at interlocking switches and signals were made in France in 1855 and in Britain in 1856. Interlocking at crossings and junctions prevents the signalman from displaying a clear signal for one route when clearance has already been given for a conflicting route.

Another forward step was the introduction of train operation on the distance interval or block system. The electric tablet machine (1878) for the safe operation of traffic over a single track was another noteworthy development.

The next major step forward was the application of power to signaling. Experience gained with large power interlocking frames having mechanical interlocking between levers led to the development of all-electric interlocking. This, in turn, led to relay interlocking in which interlocking and controls are effected by electrical relays.

A development in the design of the signal itself was the introduction of the colour-light type in addition to the semaphore pattern. The colour-light signal uses a separate bulb and lens for each aspect. By the 1960s it was being generally superseded in the U.S. by the searchlight type, which uses only a single lens and bulb, the different colours being displayed by means of roundels or colour filters that are rotated in front of the lamp. Two other types of signals are used in the

U.S.: the position light, in which rows of yellow lights duplicate the positions of semaphore arms, and the colour-position signal, which uses coloured lights arranged in rows.

Most lines in Europe are controlled from wayside signal towers, or cabins at stations, in conjunction with fixed signals. Block signaling is usual, the track being divided into sections, and a train is not permitted to enter a section until the train ahead has left it. This manual block system was once much used in the United States also, and is still found there on some lines. Electric interlocking improves this system by making it impossible for the "line clear" indication to be given for a section already occupied by a train.

Of more recent introduction is automatic block signaling. This uses track circuits which are short-circuited by the axles of a train, putting the signals in the rear of the train (and, on single track, in front of it as well) at the danger aspect. A track circuit is made by the two rails of a section of track, insulated at their ends. Electric current, fed into the section at one end, flows to a relay at the opposite end and the wheels of any vehicle will then short-circuit the current supply and de-energize the relay.

Signaling on African, Asian and Australian systems usually follows European practice in areas of heavy traffic. On lines of lighter traffic, control is often via the telegraph or telephone.

In the early years of U.S. railways, it was common to program operations on the basis of a strict timetable, which set up all the places where trains were to meet. If one train were delayed, others would also be held up, since it was impossible to change the meeting points.

By using the telegraph it became possible for the dispatcher to issue orders to keep trains moving in unusual circumstances, or to operate extra trains when required. This "timetable-train

						
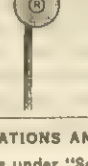

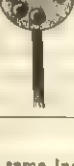

NAME	INDICATION	SEMAPHORE	COLOUR LIGHT	SEARCHLIGHT	POSITION LIGHT	COLOUR-POSITION LIGHT
CLEAR	PROCEED

STOP	STOP					

FIG. 2.—STANDARD AMERICAN SIGNAL INDICATIONS AND ASPECTS

Lamp colours: G, green; Y, yellow; R, red; W, white. The three columns under "Semaphore" show how the same indication may be given with one, two or three signal heads on the same mast (any of the other types of signal may also be combined in the same fashion); two- and three-head signals ordinarily are used at junctions, passing sidings, etc. A stop-and-proceed signal is designated by a number plate on the mast below the signal head, by a marker light, by a pointed semaphore blade or by a combination of these features

order" system is still used on about 100,000 mi. of lighter-traffic line in the U.S. and on much Canadian mileage. It is widely supplemented by automatic block signals, which provide an additional safety factor.

TABLE V.—Standard U.S. Locomotive Whistle Signals

Sound	Meaning
—	Apply brakes; stop
— —	Release brakes; proceed
— . . .	Flagman protect rear of train
— — — —	Flagman return from west or south*
. . . — — —	Flagman return from east or north*
. . .	Engineman's answer to any signal not otherwise provided for
. . . .	When standing: will back up. When running: will stop at next passenger station
— . . .	Call for signals (usually to request towerman or operator to clear a signal so train can proceed)
— . . . —	Another section of this train is following
— — — —	Approaching public crossing at grade
— — — — —	Approaching station, junction or railway crossing at grade
— — .	Approaching a meeting or waiting point

*Followed by one or more short sounds to designate which track is meant, when train is in multiple-track territory

The earliest function of signaling was to advise the engineman when it was unsafe to proceed and to indicate where a train should stop. In contrast, the aim of modern signaling is to keep trains running to the best advantage. Route-setting is one of the developments that helps accomplish this. With it, a complete route can be set up by operating push buttons on an electrical control panel. Equipment of this kind allows a large area to be controlled from one point, thus reducing the number of signal towers and personnel required.

1. Centralized Traffic Control.—A logical extension of the route interlocking principle is centralized traffic control (C.T.C.). This is a system in which trains are operated entirely through remote control of the switches and signals from a central point by an operator, who sees the track layout in miniature on his control panel. Lights on the panel show the location and progress of all trains at all times. By pushing buttons and turning levers, the operator directs the movement of trains over distances from a few miles to several hundred miles.

TABLE VI.—British Locomotive Whistle Signals

Sound	Meaning
—	Approaching signals at "danger" or to indicate when ready to proceed on same track (on main or fast lines)
— —	As above, when on slow, or freight, track next to main line
— — —	As above, when on track next to slow or freight line (one additional long sound is given for each additional line farther away from the main line)
— .	On main line and requiring to proceed to the left
— . .	On main line and requiring to proceed to the right
— — .	On slow or freight line and requiring to proceed to the left
— — . .	On slow or freight line and requiring to proceed to the right
. . . .	Requiring to pass between slow line or loop and main line
.	Requiring to cross from main to main
(crow)* —	Requiring to pass between bay and platform lines
. . . .	Train ready to leave siding
. . . .	Shunt from sidings to main line
(three crows)	To or from locomotive
(crow) — (crow)	Express train requiring fresh locomotive at next stopping place
— . . .	Fire on trackside
(crow) .	Locomotive requires water
. . . .	Locomotive clear of switch which requires turning
. . . .	Train or locomotive shunted clear of switch leading from one running line to another
(2 crows)	Train or locomotive shunted clear of all running lines
	Preparing to start train assisted by locomotive in rear

*Crow: the traditional "cock crow" indication, thus: —

In C.T.C., track circuiting is essential so that the position of every train is known. Switches and signals are operated by coded electrical circuits which reduce the wiring required. C.T.C. is being used on an increasing scale in Africa, Asia and New Zealand as well as in certain European countries. Over long distances, C.T.C. substantially increases track capacity by making more effective use of the line.

Since C.T.C. eliminates any need for written train orders or manual operation of block signals, it permits closing of telegraph or signal stations—another major economy. On lines of light traffic,

most of the benefits of C.T.C. can be obtained at less cost by having the signals controlled from the central office and the switch points operated manually by the train crews.

2. New Forms of Signaling.—Completely automatic signaling, activated by electronic program machines, had been introduced by the 1960s on some of London Transport's subway lines. The program machine has a plastic band incorporating a complete timetable translated into a series of punched holes. The line of holes is positioned for each train by a photoelectric cell. A comb with steel "feelers" scans the line of holes, causing a series of electrical contacts to be closed; these in turn carry out all signal, switch and interlocking movements.

In Germany, experiments were being conducted with train control by radio signals to the enginemen, instead of by fixed wayside signals. Signal indications are given on a panel in the self-propelled car or locomotive and are accompanied by tone signals. Orders are acknowledged by a train recognition signal and the position of the train on the line is visually presented to the control operator on a track panel. In addition, all locomotives and self-propelled cars are linked to the controller by radio telephones.

3. Automatic Train Controls.—Automatic train control (A.T.C.) provides the engineman in the locomotive cab with audible (and sometimes visual) information on track conditions. Should a restrictive indication be ignored, the brakes are applied automatically to stop the train. Several U.S. railways use automatic speed control, a refined form of A.T.C. A miniature signal in the cab repeats the wayside signal aspects (or it may take the place of wayside signals). Should train speed exceed that indicated by the aspect being displayed, the brakes are automatically applied to reduce the speed below the permissible level.

4. Automation of Train Operations.—Only a slight further extension of this type of control is needed to permit fully automatic operation of the train—dispensing entirely with the engine crew. From a technical standpoint, fully-automatic train operation is entirely feasible, and experiments have been made with automatic or remote control of locomotives and trains. The French railways controlled an electric train by radio and also conducted trials with a radio-controlled diesel switching locomotive. The German Federal railways carried out experiments with a radio-controlled electric switching locomotive.

The Russian railways were investigating the problem of operating trains automatically with the object of saving electric current and increasing track capacity. The basis of the system is an electronic computer into which is fed data relating to the weight and resistance of the train, the characteristics of the line, the tractive effort of the locomotive and any variable information such as weather conditions, temporary speed restrictions, etc. The system can be adapted to both diesel and electric traction. It is not intended to dispense with the engineman, but his work would be reduced to watching the line ahead in case of emergencies.

In North America, several mining and industrial railways began using fully automated, crewless trains in the regular operation of shuttle runs. A subway shuttle train in New York city was automated and ran successfully for several years. Labour union opposition seemed likely to delay for some time the automation of intercity common carrier railways. However, because of the guiding action of the flanged wheels on the rails, railways are ideally suited to fully automatic operation. Under the pressure of competition, they may be expected to move in this direction. Indeed, the extent to which railways would be able to automate their operations seemed likely to be a major factor in determining how important a role they would play in the world economy during the last decades of the 20th century.

VIII. CLASSIFICATION (MARSHALING) YARDS

A freight train starting on its run usually consists of cars moving to a number of different destinations. Somewhere en route, the cars going to each destination must be sorted out and transferred to other trains going to the proper terminals. This is done in classification or marshaling yards. In the years following World War II, railways made much progress in improving the ef-

iciency of these yards—mainly through the use of automatic equipment.

Most large classification yards have a hump over which cars are pushed. The cars then roll down the hump by gravity and each is routed into a classification track corresponding to its destination. The principle is similar to that of sorting letters into pigeon-holes at a postoffice.

The speed of a car rolling down the hump siding can be controlled by retarders—electric or electropneumatic clamps that grip the wheels of the car as it passes over them. The degree of retardation can be controlled automatically by an electronic computer which takes into account such factors as the weight, speed and rolling friction of the car. Equipment of this kind enables more cars to be handled, reduces human error, lessens the risk of damage to cars and their loads, and reduces delays.

However, modern improvements involve more than just the automatic humping of cars. The modern electronic yard is usually blanketed with a local radio network, as well as telephone, teleprinter and pneumatic tube communication circuits. Television may be used to scan trains entering or leaving the yard. Infrared detectors scan the wheels of incoming trains to pick out any journal bearing that may be overheated. Repair shops adjacent to the yard are mechanized to speed the repair of cars found to be in bad order as they move over the hump. In a fully modern hump yard it is not unusual to classify a train and have the cars moving in outbound trains in less than two hours.

Because modern classification yards can sort cars with such efficiency, they eliminate the need to do this work at other, smaller, intermediate yards. Thus, one modern hump yard may permit curtailing or closing a dozen or more other yards. Most of the modern yards built in North America have paid for themselves in operating savings in three or four years, and this takes no account of the benefits of improved service to shippers.

IX. CO-OPERATION AMONG RAILWAYS

In both North America and Europe, close working relations among different (and often competing) railway systems developed almost from the earliest years. It was found desirable, for instance, that connecting railways agree on such basic elements as the gauge of track and the type of couplings to be used on cars. This was done to such an extent that a shipper can send a carload of his goods from almost any railway point in North America to any other point; and a passenger may buy, at his local railway agency, a ticket for a trip that may cover thousands of miles in the cars of many different railways.

1. North American Organizations.—The principal element for co-ordination among North American lines is the Association of American Railroads (A.A.R.), with headquarters in Washington, D.C. Members of the A.A.R. include about 185 of the principal railways in the U.S., Canada, and Mexico. The American Short Line Railroad association is a similar organization serving 275 smaller lines. In addition, railways and the companies that supply them with materials and equipment work together through numerous regional groups and trade associations.

Through its several divisions and their numerous working committees, the A.A.R. co-ordinates the operations of the individual companies that make up the North American rail network. Among results of this joint activity (by the A.A.R. and its various predecessor groups) are standard items of car equipment, such as couplers, brakes and safety appliances; standard time; standard train operating rules; standard rules governing the interchange of cars among railways; and rules covering the collection and division of revenues for interline movements of freight and passengers.

Through its research centre at Chicago, the A.A.R. also carries on technological research and testing; this is in addition to the testing and research work done by many individual railway companies. The A.A.R. also represents the U.S. railway industry in connection with legislative proposals in congress that may affect the railways, and it carries on an extensive public relations program for the industry as a whole.

Although the Canadian and several U.S. railways operate their

own sleeping cars, most cars of this type are operated by the Pullman company, which is jointly owned by the principal railway companies. A similar jointly owned company, the Railway Express Agency, Inc., handles most express package traffic. This agency uses both railways and other types of transport; it has an active air express division.

A number of companies also own large fleets of freight cars but do not actually operate any railway line. These so-called private car lines were formed usually to meet the need for certain specialized types of equipment that could be better supplied in this way than by the individual railways.

Railways also co-operate throughout the western hemisphere through the Pan American Railway Congress association, which has its headquarters at Buenos Aires, Arg. It operates much like the International Railway Congress association (which has worldwide membership), that is, through the exchange of technical information among railways in the different North and South American countries.

2. European Organizations.—In Europe, too, the gradual spread of railway routes led to the need for some form of co-operation and uniform regulations relating to the movement of equipment. From this need came the Convention Internationale sur le Transport des Marchandises, or International Convention for the Transport of Freight (C.I.M.), which was established in 1890.

Later came the Convention Internationale sur le Transport des Voyageurs, or International Convention for the Transport of Passengers (C.I.V.). These were followed by the Regolamento Internazionale Veicoli, or International Wagon union (R.I.V.), and Regolamento Internazionale Carrozzi, or International Carriage and Brake Van union (R.I.C.). They succeeded earlier arrangements concerning the international movement and interchange of passenger and freight vehicles. From these arrangements also came annual passenger and freight train timetable conferences.

In 1885 the International Railway Congress association was formed for the purpose of exchanging technical information between administrations, and in 1922 the Union Internationale des Chemins de Fer, or International Union of Railways (U.I.C.), was created. Its original aim was to improve international services. During the interwar years it was also concerned with technical measures and joint regulations for improving international traffic.

After World War II, European railway co-operation made great strides in many different spheres and, in particular, the scope of the U.I.C. was considerably enlarged. From the U.I.C. sprang a number of other organizations that made important contributions to the economy and progress of the European railway systems.

The Europ freight car pool came into being in 1953. Previously, freight cars entering another country had to be returned to the owning system as quickly as possible after unloading, subject to efforts being made to find a return load. Europ cars are not bound by this requirement, which saves millions of empty car miles a year.

Interfrigo was created in 1949 with the object of developing the international transport of perishable traffic at controlled temperatures. It is owned jointly by 11 railway systems, and there are agreements with nonmember administrations. Interfrigo has a fleet of 900 vehicles and, in addition, operates in international traffic some 10,000 refrigerated vehicles belonging to members and their subsidiaries.

The Office for Research and Experiments (O.R.E.) was created by the U.I.C. in 1949. Its purpose is to conduct research and tests for the benefit of members. Unlike the Association of American Railroads, O.R.E. does not have its own research establishment. Instead, it uses the laboratories and testing plants of its members. Financing is handled by a common fund, the cost being divided among the 29 members in proportion to the operated track mileage of each.

Eurofirma is a financing company that was established in 1955 with about 16 administrations as members. It finances the purchase of locomotives and rolling stock.

Trans-Europ express (T.E.E.) services are operated jointly by the Dutch, Swiss, German, French and Italian railways. They consist of a network of international express trains linking important cities in eight countries. Operations commenced in 1956. The trains are owned by the different administrations but must conform to accepted standards of comfort, speed, etc. The first trains were all diesel-powered, but in 1959 the Swiss ordered trains capable of running on four different electric traction systems for operating T.E.E. services.

Although it is a private company, the Compagnie Internationale des Wagon-Lits (C.I.W.L.) occupies a unique position in the field of international passenger services in Europe. It has been engaged in the operation of sleeping cars on international services since 1876. It also operates dining cars, Pullman cars, buffet and light refreshment facilities, restaurants at stations and airports, a motel, and restaurant and cabin facilities on river steamers. The company is registered in Brussels and has its operational and administrative headquarters in Paris. Its activities, although concerned principally with Europe, also extend to Africa and the middle east.

X. CONCLUSION

The railways can look back over a proud history. They were a vital element in the industrial revolution. They helped make Britain an industrial power, played similar roles in countries such as France and Germany, and went on to do much the same in Russia. Railways literally built the United States and Canada, and they remained the economic backbone of most of the major world powers.

But the railways in a number of countries—especially in Britain and the United States—were in serious trouble by the 1960s: they were steadily losing traffic to other modes of transport. In most countries, the railways had long since come under state control, and the remaining privately owned lines were finding it difficult to operate at a profit. Railway mileage was shrinking in many countries. Did this foretell the end of this great form of transportation?

Technology was evolving so rapidly that it was probably unwise to say that this could not happen. However, as of the 1960s, it seemed unlikely. No other form of transportation had yet been developed to the point where it could challenge the railway as an all-around carrier.

Railways still offer two major advantages: (1) At distances of more than 100 or 200 mi., they can haul any kind of freight, as well as passengers, at a true cost lower than any other form of transportation on land or air; (2) They are all-purpose land carriers. Pipelines may carry liquids and some solids economically; airplanes may produce savings on very high-value commodities; trucks offer speed and flexibility for relatively short hauls; overland conveyor belts may prove of value for certain bulk commodities. But only railways can carry anything, almost anywhere—and do it with little regard for weather conditions.

In sum, the railway is one of the earliest and greatest material achievements of the industrial era. It seemed likely to continue serving man's evolving civilization for many years to come.

RAILWAY, TUBE: see SUBWAY (UNDERGROUND RAILWAY).

RAIMONDI, MARCANTONIO (called MARCANTONIO) (c. 1480–c. 1534), Italian engraver, outstanding Italian master of engraving of the Renaissance and the first who practised it to reproduce designs of other artists rather than his own. He received his training in the workshop of the famous goldsmith and painter Francesco Raibolini, called Francia. There, according to Vasari, "he made waist buckles and many other things in niello . . . being in truth most excellent in that craft."

The real fame of Raimondi was to be founded on his attainments in that particular development of the goldsmith's art which consists of engraving designs on metal plates for printing. About 80 engravings can be attributed to the first six years of his career (1505–11). They include many subjects from mythology and some of religious character. Figures, drapery and composition bespeak the influence of Francia, but the landscape backgrounds and the expression of form by light and shadow indicate German traditions as well. Perhaps for commercial reasons or to improve his style, he produced a series of counterfeits of copper engravings from Albrecht Dürer's woodcuts. There are 69 of these: 17 from the "Life of the Virgin," 37 of the woodcut "Little Passion" and a few others. The "Life of the Virgin" was copied in 1506 and signed with Dürer's signature. Dürer, traveling in Italy in the same year, complained to the Venetian senate and Raimondi added his own signature to the copies he subsequently completed in 1510 of Dürer's "Little Passion." Raimondi profited greatly by these studies of Dürer's energetic line and his use of crosshatching in modeling. He was to make brilliant use of these under another influence. Until this time he had lived only in Bologna, with the exception of a visit or visits to Venice.

Soon he was attracted to the circle that surrounded Raphael in Rome. Where or when he met Raphael is uncertain. His passage to Rome by way of Florence was supposedly marked by an engraving (1510) known as "The Climbers" (*Les Grimpeurs*), in which he reproduced part of the design of Michelangelo's cartoon of soldiers surprised while bathing, he added behind the figures a landscape imitated from the young Dutch engraver Lucas van Leyden. The piece in which he is recorded to have first tried his hand after a work of Raphael is the "Lucretia." Raimondi was almost exclusively engaged in engraving the designs of Raphael or of his immediate pupils. Raphael, the story goes, was so delighted with the print of the "Lucretia" that he later personally trained and helped Raimondi.

A printing establishment was set up under the charge of Raphael's colour grinder, Baviera, and profits in its early days were shared by the engraver and the printer. The sale soon became very great; pupils gathered about Raimondi, of whom the two most distinguished were Marco Dente, known as Marco da Ravenna, and Agostino De Musis, known as Agostino Veneziano. During the last 10 years of Raphael's life and for several years following his death, the group produced a great number of engravings after the master's works. They did not usually copy his finished paintings, but worked up (with the addition of simple backgrounds and accessories) his sketches, which often gave the composition in a different form from the finished work, and are all the more interesting on that account.

Raimondi's best engravings (e.g., "Massacre of the Innocents")

were done during the first years after he had attached himself to Raphael. In them he entered into the genius of his master and lost little of the chastened science and rhythmical purity of Raphael's contours. In the parts where he was left to himself (the rounding and shading, the background and landscape) he managed his burin with all the skill and freedom he had gained by the imitation of northern models, while dispensing with the northern emphasis and redundancy of detail. Raimondi's engravings after the works of Raphael's later years were colder and more ostentatious. Still more so, as is natural, were those which he and his pupils produced after the designs of the followers of Raphael and Michelangelo, such as Giulio Romano, Polidoro Baccio or Bandinelli.

Raimondi's association with Giulio Romano (*q.v.*), was the cause of his first great disaster in life. He engraved a series of obscene designs by that painter in illustration of the *Sonnetti lussoriosi* of Pietro Aretino which caused his arrest. Marcantonio's ruin was completed by the calamities attendant on the sack of Rome, by the German troops of the emperor Charles V of Spain in 1527. He had to pay a heavy ransom to escape the Spaniards, and fled, to quote Vasari, "all but a beggar." It is said he took refuge in his native city of Bologna, but he never again emerged from obscurity. All that is known with certainty is that in 1534 he was dead.

RAIMUNDO, DON (d. 1152), archbishop of Toledo from 1125 to 1152, was one of the many French monks who went to Spain with Bernard of Périgord (archbishop of Toledo, 1085–1124) in the time of Alfonso VI. He was appointed bishop of Osma (1109), but was dispossessed and imprisoned (1111) by Alfonso VI's successor Alfonso I of Aragon, for opposing the marriage of Alfonso I with Alfonso VI's daughter Urraca. This persecution commended him to Alfonso VII, whose chancellor he became. On Bernard's death he was appointed to succeed him as archbishop of Toledo and primate. Raimundo's main importance is in the history of medieval learning; it was under his patronage—and probably as a result of his encouragement—that the famous Toledan school of translators came into existence. Already some effort to make available to Christians the learning of the Spanish Arabs had begun, notably under the aegis of Miguel, bishop of Tarazona (1119–51). Raimundo was, however, made aware that there were still in Toledo not only a great many Arabic and Jewish works on science, mathematics, and philosophy unknown to Christian scholars but also learned Jews, Mozarabs, and Muslims able to read them. The archbishop—who was without his predecessor's fanaticism—either saw for himself, or was persuaded of, their importance. He, therefore, encouraged Spanish scholars, especially converted Jews, to translate them into Latin; soon foreign scholars arrived in Toledo to commission translations or investigate the material available there and in Spain generally. Raimundo's patronage was sometimes acknowledged in the dedications of their translations. One of the earliest Toledan translators, Johannes Hispanus, was as much interested in astronomy and astrology as in Arabic and Jewish philosophy, but Raimundo's own patronage was especially reserved for philosophical translations such as that of the *Fons Vitae* of Ibn Gabirol and Neoplatonic works generally. The Toledan translators, subsequently associated with a flourishing cathedral school, went on working for three centuries.

See Ángel González Palencia, *El arzobispo don Raimundo de Toledo* (1942). (P. E. R.)

RAIN: see METEOROLOGY; RAINFALL.

RAINALD OF DASSEL (c. 1118 or 1120–1167), German statesman and military leader, chancellor of the Holy Roman Empire and archbishop of Cologne, was the second son of Count Rainald I of Dassel. After attending the school at Hildesheim, he studied at Paris, probably c. 1140–46 and under the English dialectician Adam du Petit-Pont. In the following years he became provost of four churches, including two in Hildesheim, and in 1153 he refused an offer of the bishopric. Apparently his ambitions were already fixed on the imperial court, to which he had been intro-

duced by the statesman and diplomat Wibald of Stablo. By the end of 1154 he was prominent in the entourage of the emperor Frederick I (*q.v.*), and in May 1156 he was appointed imperial chancellor. From then until his death he played a leading part in the formation and execution of imperial policy.

At the Diet of Besançon (October 1157) Rainald "exposed" and "interpreted" the letter in which Pope Adrian IV referred to the empire as a *beneficium* conferred by the pope; and he then directed a dashing propaganda campaign on behalf of the empire. Between 1158 and 1164 he several times led troops to Italy and negotiated with towns on Frederick's behalf. In 1159 he was elected archbishop of Cologne. In the same year Pope Adrian IV died, and Rainald championed the emperor's antipope Victor IV against Alexander III, going on missions to the kings of France and England in 1160, 1162, and 1165, and asserting that the bishop of Rome was in the same relationship to the emperor as any French bishop to the French king. Excommunicated by Alexander III in 1163, he ensured the continuance of the schism by rushing through, on his own responsibility, the election of a new antipope on the death of Victor IV. It was he also who secured the canonization of Charlemagne in 1165. On May 29, 1167, he won, with a small force, a decisive victory over the Romans; but on reaching Rome he was afflicted, like most of the imperial army, with malaria, and he died on Aug. 14, 1167. He was buried in Cologne Cathedral, to which he had given the relics of the Magi (received by him as part of the loot of Milan). He had been the mainspring of Frederick I's imperial policy in Italy.

RAINALDI, CARLO (1611–1691), Roman Baroque architect, noted particularly for his works of the 1660s, was born in Rome in 1611 and died there in 1691. He collaborated with his father, Girolamo Rainaldi (1577–1655), a distinguished architect who transplanted to Rome the north Italian Mannerist tradition of Pellegrino Tibaldi. After his father's death, Rainaldi evolved a monumental grand manner, without entirely discarding his paternal heritage. The final building of his masterpiece, Sta. Maria in Campitelli (1663–67), showed a north Italian rather than a Roman pedigree. The use of many freestanding columns gave the building a scenographic quality which had neither past nor future in Rome but influenced late Baroque north Italian church design. Nor was the facade, closely set with columns, rooted in the Roman tradition. Again, its basic motif—two enormous aediculae, one set into the other—was current in northern Italy.

Rainaldi's last important work was the grand facade uniting the old apse of Sta. Maria Maggiore with the chapels of Sixtus V and Paul V (1673). Thenceforth his practice was confined to a number of smaller enterprises. (Rf. W.)

RAINBOROW (RAINBOROWE or RAINBOROUGH), **THOMAS** (d. 1648), English soldier and republican who fought for Parliament during the Civil War, spent his youth as a sailor and after the outbreak of war commanded the "Swallow" in the parliamentary fleet in 1643. He was soon transferred to the land forces and became a colonel first in Lord Fairfax's army and then under the earl of Manchester. In 1645 he commanded a regiment in the New Model Army and fought at Naseby (June 14, 1645) and at the siege of Bristol. He became M.P. for Droitwich in 1646. Rainborow took a prominent part in the debates in the army council (October–November 1647) concerning the army's negotiations with Charles I and was a leader of the republican officers and a supporter of the Agreement of the People, which called for manhood suffrage and religious toleration. This caused a rift between Rainborow and the army commanders, but in December 1647 he was reconciled with Oliver Cromwell. In January 1648 he returned to sea as vice-admiral, but failing to gain the goodwill of his officers he returned to the army after five months. Appointed commander for the siege of Pontefract Castle, he was mortally wounded when royalists tried to capture him at Doncaster on Oct. 29, 1648.

See H. R. Williamson, *Four Stuart Portraits* (1949). (S. R. Br.)

RAINBOW, a name for a set of coloured arcs seen against the sky whenever falling water droplets (from a rain cloud or in a spray of a waterfall or fountain) are illuminated by a strong light source (the sun or the moon).

The bows appear as concentric arcs, with the common centre on the line connecting the eye of the observer and the light source. Most frequently only one bow is clearly visible. It appears on the opposite side from the source; its angular radius of the red border is about 42° . Other colours of the spectrum can be seen inside of this border, ending with the violet. Occasionally another, secondary rainbow is observed above the primary rainbow. Its angular radius is about 54° , and the sequence of the colours is reversed: the red is inside and the violet on the outer border of the bow. The space between these two bows seems to be relatively dark. The centre of these bows is, angularly, as far below the horizon as the source (the sun) is above. Hence, usually less than a semicircle of these coloured arcs is visible. However, if the droplets are illuminated by a reflected source from a large water surface, the rainbow will appear as arcs of circles, with the centre above the horizon. Such a reflected rainbow will intersect the ordinary rainbow at the horizon.

Inside of the outer border of the primary rainbow, additional coloured bows can be sometimes seen, called (improperly) supernumerary bows. The appearance of these bows depends primarily upon the size of the droplets; thus it varies quite considerably. When superposed on the ordinary rainbow, these supernumerary bows cause eventually a broadening or disappearance of any particular colour in the rainbow, which then results in a great variety in the brightness and purity, as well as in the angular width of coloured bows. In particular, if the water droplets are very small (of a diameter of 0.1 mm. or less), the superposition of the ordinary and supernumerary bows leads to an almost white rainbow, sometimes known as Ulloa's ring or a fogbow.

The rainbow was first correctly explained by M. A. de Dominis in 1611. The primary bow is formed by two refractions and one internal reflection in the water droplets, the secondary bow by one more additional internal reflection. This explanation was further developed and experimentally confirmed by Descartes (1637). The explanation of the colours in the rainbow was given later by Sir Isaac Newton. The supernumerary rainbows were explained much later by Thomas Young (1803) as the interference effect of two ray systems in the inner space of the bows; the mathematical theory was given by Sir George Biddell Airy (1838).

The original explanation of the rainbow by De Dominis and by Descartes is based on tracing the path of a light ray falling on

SCHEMATIC DIAGRAM OF THE ORIGIN OF THE PRIMARY AND SECONDARY RAINBOW. D IS THE ANGLE OF MINIMUM DEVIATION OF EMERGING RAYS

The light emerging from the droplets after one internal reflection will have the greatest intensity in the directions forming such a cone with the angle of 42.4 in the red and of 40.6 in the violet. The observer will see bright arcs of all spectral colours from the red over yellow, green, blue to violet. Since the angle for the red is greater, the red arcs will form the outer border, the violet arcs the inner one. The display fits the description of a primary rainbow. Similarly the secondary rainbow can be explained as consisting of Descartes rays from two internal reflections; the angle between the axis of the corresponding cones and the rays is 50.4 for the red and 53.6 for the violet. The secondary bows appear above the primary, and the sequence of the colours is reversed. (See fig.) The rays from the droplets above the primary and below the secondary bow would have to have the deviations smaller than the corresponding Descartes rays if they were to reach the observer's eye. This explains the dark space between these two bows. The tertiary and quaternary bows are quite faint and thus difficult to see against the bright sky in the vicinity of the sun.

The rays incident on the sphere on either side of the Descartes rays emerge only on one side of the minimum deviation. In this region the two systems of rays are crossing each other. Their superposition leads necessarily to interference patterns, with alternative maxima and minima of intensity in different directions. For a particular colour the positions of these maxima and minima are strongly dependent upon the size of the sphere, being closer for larger diameters of the sphere. The main maximum is usually close to the primary rainbow.

The superposition of the secondary maxima and minima is responsible for the great variation in the brightness and in the width of individual coloured arcs in the rainbow. If, for example, the secondary maximum in the red falls in the direction of the green arc in the primary rainbow, the mixture of these two colours produces an additional yellow arc; in the rainbow the yellow arc has enlarged width compared to that of other colours. For smaller droplets the secondary maximum in the red may be shifted beyond the blue or violet of the primary rainbow, thus giving rise to a supernumerary bow.

BIBLIOGRAPHY.—More detailed description and the theory of rainbow can be found in J. M. Pernter and F. M. Exner, *Meteorologische Optik*, 2nd ed. (1910); W. J. Humphreys, *Physics of the Air*, 3rd ed. (1940); H. C. van de Hulst, *Light Scattering by Small Particles* (1957).

RAINFALL or snowfall usually occurs from fairly thick cloud systems fed by ascending moist air. In its ascent the air expands as a result of the decreasing pressure with height and cools adiabatically (see **ADIABATIC PROCESSES IN ATMOSPHERE**). Water-vapour saturation is reached and maintained, accompanied by the production of great quantities of liquid water droplets or ice crystals.

In such active clouds the physical processes required for growth

n	Minimum deviation (D)	
	Red (656μ) ^a	Violet (397μ)
Primary rainbow	137.6° ($\pi - 42.4^\circ$) [†]	130.4° ($\pi - 40.6^\circ$)
Secondary rainbow	230.4° ($\pi + 50.4^\circ$)	233.6° ($\pi + 53.6^\circ$)
Tertiary rainbow	317.5° ($2\pi - 42.5^\circ$)	322.1° ($2\pi - 37.9^\circ$)
Quaternary rainbow	402.8° ($2\pi + 42.8^\circ$)	408.6° ($2\pi + 48.6^\circ$)

^a $\mu = 10^{-4}$ cm.

[†] $\pi = 180^\circ$.

a transparent sphere with the use of the laws of geometrical optics. From the law of refraction and reflection it is easy to determine the deviation of the emerging ray from its original direction of incidence.

The angle of this deviation depends upon the angle of incidence, the number of internal reflections n and the index of refraction of the medium inside the sphere. For a particular angle of incidence the deviation has a minimum, given in the table.

The light emerging from the sphere reaches a high intensity around the direction of minimum deviation; the intensity then gradually decreases as the deviation increases. There are, however, no rays, hence no intensity on the other side of this direction (for smaller deviations). The observer will then see the highest intensity looking against the rays having minimum deviation, called sometimes Descartes rays. The Descartes rays from all individual droplets will form a cone with the vertex in the observer's eye and with the axis in the direction from or toward the source—the sun.

of the cloud droplets or crystals to raindrops or snowflakes are accomplished easily. Meteorological evidence indicates that the ascending motion is far more important than the minutia of precipitation physics in determining when and where the precipitation will occur. Radiation, conduction and mixing are relatively inefficient atmospheric cooling processes, producing the less spectacular forms of condensation, such as dew, frost, fog and drizzle. Air cooled by lifting may be internally stable and require forced lifting, such as produced by mountains, or it may be potentially unstable and require only an initial impulse to establish free convection.

Raindrops have limited fall velocities and may be deposited some distance downwind from their point of formation, but, in general, rates of precipitation are closely related to rates of ascent. Rapid and extensive lifting by free convection in unstable air masses produces the intense rainfalls associated with showers and, in the warmer, more humid air masses, thundershowers.

Lifting processes are represented by air gliding upward over mountain slopes or over wedges of cooler air, free convection, underrunning by cooler wedges of air and large-scale net horizontal inflow of air at lower levels. The last is the most effective natural lifting process, since large masses of air are forced upward. Any or all of the lifting processes may operate on stable or unstable air within the life cycle of one major rainstorm. Orographic lifting of stable air gliding upward over gently sloping cooler wedges of air produces the typical winter rains, which are uniformly light, steady and extensive. The flash floods of the southern United States represent the other extreme, in that highly unstable and very moist maritime air is lifted by the combined effects of horizontal convergence, upglide over cooler continental air and orographic lifting.

Forced lifting of maritime westerlies produces more than 100 in. of rainfall a year on many windward points on western mountain ranges, leaving some leeward continental areas with ten inches or less per year. Rainfall is greatest on windward coastal slopes, near warm tropical waters and in areas of marked cyclonic activity. Rainfall is least near the centre of continents, in colder higher latitudes, leeward of mountain ranges and within areas of persistent anticyclonic activity.

Mt. Waialeale, Hawaii, with a 20-year average of 460 in. from tropical easterlies, is the wettest known point. The nearest competitor is Cherrapunji, Assam, with an annual average of 450 in. from the moist tropical monsoon. Less than 10 in. and more than 60 in. per year represent approximate extremes of rainfall for all of the continents. Rainfall is slight in the central regions of the subtropical anticyclones, which are therefore the desert regions of the earth. In parts of the desert no appreciable rain has ever been observed.

Over most of Europe, South America, eastern North America and central Africa the annual rainfall exceeds 20 in., while over most of Asia, excluding India, Tibet and China, the annual rainfall is less than 20 in., being less than 10 in. in a long tongue extending from Arabia across to northeast Mongolia. The central regions of Australia, most of northern and a part of southwest Africa, portions of the intermontane area of the United States, portions of the west central coast and southern east coast of South America also have less than ten inches of rain in the year. Portions of the west coast of Africa, between the equator and 10° N., a strip of the west coast of India, parts of Assam, a coastal strip of Burma, windward mountain slopes in the temperate latitudes of North and South America and many isolated tropical stations average more than 100 in. of rain in the year. Rainfall intensities greater than 1 in. in five minutes, 4 in. in one hour or 20 in. per day are quite rare, but these intensities on occasion have been more than doubled for the respective durations.

The measurement of rainfall over an area by means of a network of rain gauges is often unsatisfactory because large variations in the amount of rainfall occur between adjacent gauges. This defect can be partly remedied by the use of a 3 to 10 cm. radar, which can give an areal picture of relative rainfall intensities at any moment as far as 200 mi. away. This is possible because the amount of radar reflection from raindrops is very sensitive to

their size and number. (See RADAR METEOROLOGY.)

Average annual rainfall plus melted snow water is given in the table for some of the chief cities of the world. Data for other places will be found in standard textbooks on climatology. Detailed rainfall data for specific areas is best obtained by inquiry directed to any of the more prominent national meteorological services.

RAIN FOREST, commonly, the luxurious evergreen forest typical of wet tropical lowlands. Some authors have chosen to broaden the term to include certain forest types found in subtropical and temperate climates. Factors favourable to the development of the true tropical rain forest are annual rainfall amounts in excess of 80 in. (2,032 mm.) (with no pronounced dry season) and mean temperatures between 68° and 85° F (20° and 30° C). Rain forests are evergreen, with the dense canopy at least 98 ft. (30 m.) high, but usually much taller, and are rich in thick-stemmed lianas and in woody as well as herbaceous epiphytes.

A characteristic feature of the climax tropical rain forest is the storied or stratified layering of the dense tree canopy. The crowns of the trees usually form three distinguishable stories, but occasionally they form only two. The trees themselves are remarkably uniform in general appearance even though the number of separate species may be large (often as many as 100 distinct species of trees per acre); trunks are usually straight and slender, bases often flanged by plank buttresses; foliage consists most frequently of large, leathery, dark-green leaves with entire or nearly entire margins; flowers are usually inconspicuous. As P. W. Richards stated, "So uniform is the foliage that the non-botanical observer might easily be excused for supposing that the forest was predominantly composed of species of laurel" (P. W. Richards, *The Tropical Rain Forest*, Cambridge University Press, 1952).

Contrary to popular belief, the tropical rain forest is not an impenetrable jungle of undergrowth, creepers, and rotted vegetation. Such a description applies only along edges of clearings or banks of waterways, where the strong tropical sunlight can penetrate to the forest floor. In most cases, herbaceous ground flora is sparse and the soil bare or only thinly covered by dead leaves. An abundance of climbers is characteristic of the forest, however, in addition to almost unbelievable numbers of epiphytes, which grow on trunks, branches and even the leaves of the trees. The latter group of flora include some of the most exotic flowering plants found in any plant community.

The tropical rain forest forms an irregular belt around the earth, bisected unequally by the equator and interrupted by seas, mountains and, in a few cases, "tongues" of dry subtropical climates that here and there extend into equatorial regions. Ecologists recognize three distinct formations of tropical rain forest. These correspond to the three primary regions of the earth that possess equatorial rainy climates, and may be described as follows:

American rain forest: tropical portions of Central and South

America from the Amazon and Orinoco basins on the south to southern Mexico on the north.

Indo-Malayan rain forest: this formation extends from Ceylon and western India to Thailand, Indochina, the Philippines, and through the Malay archipelago to New Guinea. In Australia the rain forest occupies a narrow strip along the northeastern coast.

African rain forest: this formation is quite irregular; the largest portion lies within the Congo basin and along the coast of the Gulf of Guinea.

Related Types.—The changes in vegetation with increasing altitude within the tropical rain forest are as marked as in the forests of temperate latitudes. As greater altitudes are reached, the typical forest of the equatorial lowland begins to change character: trees are lower, the number of species becomes less, and finally the typical tropical flora is replaced by a mountain vegetation, where many of the species are temperate. Richards refers to this formation type as the "montane rain forest." The altitude at which this transition occurs varies markedly from region to region depending upon temperature, rainfall, exposure to winds, soil, and perhaps other factors. The base of the montane rain forest in some areas occurs at altitudes as low as 800 ft. (250 m.); in others it is as high as 4,000 ft. (1,200 m.).

In eastern Australia, southeast Asia and on the east coast of South America, the evergreen rain forest extends far into subtropical latitudes. These forests differ from the true tropical rain forest and should be considered a distinct formation type—subtropical rain forest. The species of trees decrease in number with increasing distance from the equator, and subtropical and temperate species occur together in increasing proportion. Features such as buttressing and production of flowers from main and old stems tend to disappear. Nevertheless, the forest retains much of the true tropical aspect.

One of the important subtypes of the tropical rain forest is the mangrove swamp forest found along tropical seacoasts. The marine muds of coastal tidal zones provide ideal conditions for mangrove formations. These formations, however, may also occur far inland along brackish estuaries. Standing upon stilt roots that lift the main trunk of the tree above high-water level, the mangrove forest at low water presents an impenetrable tangle of roots and knees. Mangroves are of considerable economic importance because of their role in reclaiming land from the sea and also because they are an important source of firewood, timber, and tanbark. Mangrove vegetation extends to about 32° N, and even farther from the equator in the Southern Hemisphere, but it reaches its greatest luxuriance where the tropical rain forest is the climax forest formation.

The term temperate rain forest is reserved to describe certain subantarctic broadleaf evergreen forests of southeastern Australia, New Zealand, and southern Chile, which are dominated by such temperate trees as *Nothofagus*. Rainy temperate forests of other regions, such as those of the coasts of Washington and Oregon, are occasionally referred to as rain forests, but such a usage of the term has not gained general acceptance among ecologists.

RAINIER, MOUNT: see MOUNT RAINIER NATIONAL PARK.

RAINIS (pseudonym of JĀNIS PLIEKŠANS) (1865–1929), Latvian poet and dramatist whose works were outstanding as literature and for their assertion of national freedom and social consciousness, was born at Varslavāni, Zemgale, on Sept. 11, 1865. He studied law at St. Petersburg and practised as a barrister in Jelgava, Latvia. From 1891 to 1895 he edited the newspaper *Dienas Lapa*, which initiated the so-called new movement, aimed at promoting social and class consciousness in the peasantry. Returning from a visit to Germany and Switzerland (1893) inspired by Marxist theory and writings, Rainis began his literary career as a fighter for social justice and national freedom. His own philosophy, however, showed no trace of Marxist materialism—he regarded life as an incessant series of mutations of energy. Partly because of Russian censorship, he used symbols to express

his ideal of political and personal freedom; but in 1897 he was transported to Pskov, and later to Slobodsk, for political activities. Returning in 1903, he took part in the unsuccessful revolution of 1905, after which he emigrated to Switzerland, only returning to Latvia in 1920, after it had finally achieved its independence. He was enthusiastically welcomed, elected to the *Saeima* (parliament), and was minister of education (December 1926–January 1928), and director of the national theatre (1921–25). He died at Majori, Rigas Jurmala, on Sept. 12, 1929.

Rainis' first volume of poetry, *Tālas noskaņas zilā vakarā* ("Far-Off Reflections on a Blue Evening," 1903), displays his wide experience and the nostalgia of an *émigré*, and contains some subtle love lyrics. *Vētras sēja* ("Tempests Sown," 1905), *Klusā grāmaka* ("The Silent Book," 1909), *Tie, kas neaizmirst* ("Those, That Do Not Forget") and *Vēja nestas lapas* ("Wind-Blown Leaves"; both 1911) express the revolutionary struggle through Symbolism. *Gals un sākums* ("End and Beginning," 1912) is imbued with the spirit of Hegel's dialectical philosophy. In his plays, Rainis used motifs from folklore as symbols for his political ideals: they include *Uguns un nakts* ("Fire and Night," 1905), *Indulis un Ārija* (1911), *Pūt, vējiņi* ("Blow, Breeze," 1913), *Spēlēju, dancoju* ("I Play and Dance," 1919), and *Jāzepts un viņa brāļi* (1919; *The Sons of Jacob*, 1924).

He also translated Shakespeare, Schiller, Heine, Pushkin, and Goethe's *Faust*, which enlarged the vocabulary of literary Latvian and introduced the use of shorter word forms.

See J. Andrup and V. Kalve, *Latvian Literature* (1954); *A Century of Latvian Poetry*, trans. and ed. by W. K. Matthews (1958).

(J. A. A.)

RAINY LAKE lies 150 mi. (241 km.) W of Lake Superior, partially on the international boundary between Ontario and Minnesota. The lake is 1,108 ft. (338 m.) above sea level and covers an area of 345 sq.mi. (894 sq.km.). It is 56 mi. (90 km.) long and has an average width of 5 mi. (8 km.) (maximum, 27 mi. [43 km.]). There are over 500 islands in it. The shores, characteristic of lakes on the Canadian shield, are irregular and deeply indented. Drainage is westward through Rainy River to Lake of the Woods.

Fort Frances, Ont., and International Falls, Minn., on the river at the lake's southwestern extremity, manufacture pulp.

(W. G. DN.)

RAIPUR, a municipal town and district in Madhya Pradesh, India. The town, headquarters of the district, lies 188 mi. (303 km.) E of Nagpur on the South Eastern Railway from Nagpur to Calcutta. It is also connected by rail with Vizianagram and the port of Vishakhapatnam on the east coast. Pop. (1961) 139,792. Rajkumar College, where the sons of the chiefs of the Chhattisgarh and Orissa states were educated, has been opened for general admission, and there are nine colleges including those of arts, science, law, commerce, Sanskrit, engineering and technology, and Ayurvedic medicine, all affiliated to Saugar University in the same state.

RAIPUR DISTRICT (pop. [1961] 2,002,004) covers an area of 8,214 sq.mi. (21,274 sq.km.) and occupies the south and centre of the Chhattisgarh rice plain. It includes a large area of forest which abounds in wild buffalo, tigers, spotted deer, and wild dogs. The district is extensively irrigated (more than 300,000 ac. [121,400 ha.]) and exceeds the other districts of Madhya Pradesh in this respect. It also has the greatest number of cattle and is the leading rice-producing district of the state. (D. G. NA.)

RAIS (RETZ), **GILLES DE** (1404–1440), marshal of France, satanist, and murderer, the central figure of a 15th-century *cause célèbre*, whose name was later connected with the story of Bluebeard (*q.v.*). He was born at Champtocé in Anjou in September or October 1404, the son of Guy de Laval, baron de Rais. His parents died in 1415, leaving him great wealth and possessions, and he became a ward of his grandfather, Jean de Craon. On Nov. 30, 1420, he abducted and married a rich heiress, Catherine de Thouars. He fought for John V of Brittany against the house of Blois-Penthievre in 1420 and served Yolande of Aragon, duchess of Anjou, against the English in 1427. Entering the service of Charles VII in 1429, he was made responsible by the king's

chief minister Georges de la Trémouille for the safety of Joan of Arc. He remained with her from the relief of Orléans in May 1429 to the time of her capture by the Burgundians at Compiègne in May 1430. He took part in the coronation of Charles VII at Reims (July 17, 1429) and was made marshal of France. Thereafter, Rais grew increasingly indolent and in 1434 ignored a royal order to campaign in Burgundy with Charles, duc de Bourbon. For this he was subsequently barred from holding any administrative office.

A munificent patron of music, literature, and pageants, he kept a more lavish court than the king and dissipated his wealth so rapidly that his family secured a decree from Charles VII in July 1435 restraining him from selling the rest of his estates. To redeem his fortunes Rais turned to alchemy, seeking the assistance of alchemists from all over Europe. He resorted to necromancy, satanism, and finally the torture and ritual murder of kidnapped children, perhaps as many as 200. At the same time he spent vast sums of money on the building, ornaments, and vestments of the collegiate chapel at Machecoul, near Nantes, which he founded.

In June 1440 he attacked Jean le Ferron, brother of the treasurer of the duchy of Brittany, during the celebration of Mass at a chapel in Brittany. This desecration led Jean de Malestroit, bishop of Nantes, to investigate all Rais's activities. Arrested at Machecoul in September, Rais was condemned for heresy by the bishop and sentenced to death for murder by a civil tribunal. His confession and repentance, and his resignation at his execution by hanging at Nantes on Oct. 26, 1440, were acclaimed at the time as an example of Christian penitence. His wife died in 1462.

RAISEN, a town and district in the Bhopal division of Madhya Pradesh, India. The town, headquarters of the district, lies on the Bhopal-Jabalpur road, 28 mi. (45 km.) ENE of Bhopal. Pop. (1961) 5,962. The fort, built of massive sandstone blocks, stands on a spur of the Vindhya Mountains overlooking the town. Raisen played an important part in the history of eastern Malwa (*q.v.*). In the 16th century it was the stronghold of Silhari, a Rajput chief. In 1543 the fort was conquered by Sher Shah, and during Akbar's reign it was the chief town of Raisen sarkar in the subah of Malwa.

RAISEN DISTRICT (area 3,272 sq.mi. [8,474 sq.km.]) had a population (1961) of 411,426. The Vindhyan axis passes north-east-southwest through the district, and in between the spurs are fertile basins of the Betwa, Bina, and Tondoni rivers, producing wheat and jowar. (S. M. A.)

RAISIN, the dried fruit of certain varieties of grape (*q.v.*). Raisin grapes were grown as early as 2000 B.C. in Persia and Egypt. Dried grapes are mentioned in the Bible (Num. vi, 3) during the time of Moses. David was presented with "a hundred clusters of raisins" (I Sam. xxv, 18), probably sometime during the period 1110-1070 B.C. The early Greeks and Romans adorned places of worship with raisins, and they were awarded as prizes in sporting events. Until the 20th century the chief raisin producers were Turkey, Iran and Greece; by mid-century the United States had taken the lead in production, with Australia ranking second. The United States raisin industry is located entirely in California, where the first raisin grapes were planted in 1851.

The word raisin is a contraction of the French *raisin sec*, meaning dried grape. However, by common usage only a few varieties of grapes are said to yield raisins upon drying. The three most important varieties of raisin grapes are the Thompson seedless, a pale yellow seedless grape, also known as sultana (Australia), white or oval kishmish (Turkey, Iran), sultanina (California); the muscat or Alexandria, a large-seeded variety also known as gordo blanco (Australia), white hanepoot (South Africa); and the black corinth, a very small, black seedless type, also called zante currant, staphis (Greece) and panariti. Other varieties of local importance are the round kishmish, rosaki, dattier, monukka and cape currant.

The trade name applied to a raisin may also signify the method of drying (natural, golden-bleached, sulfur-bleached, lexia), the form in which marketed (seeded, loose, layers), the principal place of origin (Vostizza, Smyrna, Malaga), the size grades or the quality grades. Natural raisins are dried in the sun in their natural condition; they are grayish-black or grayish-brown with the natural bloom intact and with a rather tough skin. Golden-bleached raisins are produced from Thompson seedless grapes dipped in 0.5% lye, exposed to fumes of burning sulfur for two to four hours and dried in a tunnel dehydrator. They are lemon-yellow to golden-yellow in colour, used chiefly in baked goods. Sulfur-bleached raisins are pretreated the same as golden-bleached, but are dried by exposure to direct sunlight. The grapes are spread on trays and left in the sun for three to four hours. The trays are then stacked and the drying is continued for several weeks in the shade. The finished product appears waxy, and cream to faintly reddish-yellow. Soda-dipped or soda-bleached raisins are from Thompson seedless grapes hot-dipped in dilute lye but not sulfured, then dried in the sun or in a dehydrator. If dried rapidly they are light amber to medium brown, moderately tender and mild-flavoured. Oil-dipped and lexias are dipped in a dilute solution of lye upon which a thin film of olive oil is floated; they are dried on trays in direct sunlight, are medium to dark brown, tender and mild in flavour.

The values below represent a composite of several reports on the nutrient content of Thompson seedless raisins containing about 17% moisture: carbohydrate 68%-71%, protein 2%-3%, fat 0.5%-3%, 1,300-1,600 calories per pound; milligrams in 100-g. portions: calcium 55-78, phosphorus 33-130, iron 1.5-3.3, potassium 700-900, sodium 52-87; vitamin A, 50 I.U. per 100 g., small amounts of vitamins B₁, B₂, B₆, niacin, biotin and a trace of vitamin C. Natural fruit acids contribute to the pleasant tartness of this delicacy. (Jo. E. B.)

RAJAHMUNDY, also known as Rajamahendravaram, is a market town in the East Godavari district of Andhra Pradesh, India. It lies on the left bank of the Godavari River at the head of the delta, 41 mi. (66 km.) W of Kakinada port and 369 mi. (594 km.) N of Madras on the Madras-Calcutta line of the Southern Railway. Pop. (1961) 130,002. The railway bridge across the Godavari there has 56 spans and is one of the longest railway bridges (9,036 ft. [2,754 m.]) in India. The town has three colleges, including a teacher-training college and a Sanskrit college for women, all affiliated to Andhra University. There are a sanatorium, a paper mill, and a crucible factory using graphite from deposits in the Godavari Valley. The town has a flourishing trade in timber and is also noted for the Central Tobacco Research Institute. (S. AH.)

RAJAPALAYAM, a town in the Ramanathapuram (Ramanad) district of Madras State, India, lies 365 mi. (587 km.) SW of Madras, and on the Southern Railway. Pop. (1961) 71,203. This is the only place in Tamilnad (the Tamil country) that is inhabited by the Rajus, a class of Telugu-speaking people who claim to be Rajputs and who are alleged to have come originally from the ancient kingdom of Vijayanagar. Physically they appear to be different from the indigenous population, fairer in skin and of stronger build; even the cattle they breed are much superior to the local varieties both in stature and in milking properties. Local availability of suitable soil has made Rajapalayam dominantly a cotton tract; and there are a number of ginning and spinning mills. A cement factory was completed in 1961. (G. KN.)

RAJASTHAN, a constituent state of the Republic of India which came into existence in March 1948, shortly after India's independence, through the merger of a number of the former Rajput princely states and the former small British province of Ajmer-Merwara. The states so absorbed included Jaisalmer, Bikaner, and Jodhpur, which covered a large part of the Thar (Indian) Desert together with the better-watered country to the east and south with the former states of Alwar, Jaipur, Tonk, Bundi, Kotah, Udaipur, and others. (See *History*, below.) After small adjustments of boundary in 1956, Rajasthan had an area of 132,152 sq.mi. (342,274 sq.km.) and was the second largest state

PRINCIPAL CITIES AND TRANSPORTATION ROUTES IN THE INDIAN STATE OF RAJASTHAN

of India; Pop. (1961) 20,155,602. On the northwest there is a long frontier with West Pakistan through the heart of the desert; on the north lie the states of Punjab (India) and Uttar Pradesh, on the southwest Gujarat, and on the southeast Madhya Pradesh. The capital is Jaipur. (See also RAJPUTANA.)

Physical Features.—The state is cut into halves by the ridge of the Aravalli Range which trends from southwest to northeast and rises to 5,650 ft. (1,722 m.) in Guru Sikhar (Mount Abu) near the southern end. The Aravallis attract a certain relief rainfall, but to the northwest the country fades quickly into the Thar Desert (*q.v.*) and the land surface drops steadily toward the Indus River. Much of this country is covered by loose sand and silt, often in movement by wind; where rocky ridges appear from beneath these eolian deposits they are of the old rocks of the Indian plateau.

The country is seamed with watercourses only rarely carrying water and often losing themselves in the desert. In the south they join up to form the Luni River which empties into the Rann of Cutch (Kutch). The desert is naturally very sparsely populated; the two chief towns of Jaisalmer and Bikaner formerly relied much on their functions as centres of camel traders. Elsewhere the people live in small villages wherever there is a little water, and some millet and fodder can be grown. Frequently the water in the wells fails or becomes saline and the settlement has to be abandoned. Nearer the Aravallis conditions improve, especially around Jodhpur. During the British regime considerable use was made of the little hill station of Mount Abu, and Ajmer

on the main railway from Bombay to Delhi has food and textile industries.

To the southeast of the Aravalli Range Rajasthan occupies a complex and varied upland region, sometimes called the Rajput Upland since it is the home of the Rajputs of colourful and legendary fame. The greater part drains northward to the Jumna-Ganges (Ganga) system, especially through the Chambal River, but in the south by the Mahi and other streams to the Arabian Sea through the Gulf of Cambay. The Rajput Upland is underlain for the most part by crystalline rocks of the peninsular Precambrian which are exposed over much of the higher ground. These rocks break down slowly to form thin and indifferent soils so that the main areas available for settlement and cultivation are small valley-plains. The whole plateau is characterized by an irregular rainfall which averages about 20 in. (508 mm.) a year or a little above but rarely as much as 30 in. (762 mm.). Crops rely on rainfall because neither the configuration of the land nor the availability of water permits large-scale canal irrigation, and there is no regular sub-surface water table to feed wells as there is in the northern plains. In good rainfall years the crop yields are excellent, and the land can support a larger population; in bad rainfall years the crops may fail entirely and famine may result. Fortunately there are two harvests, *rabi* (spring) and *kharif*

(autumn), and the failure of one does not necessarily mean the failure of the other. The staple food is millet, with wheat and barley available in small quantities from the winter harvest. Quantities of gram are grown for fodder.

Much of the upland is covered with scrub and dry forest, with some better forest in places. (L. D. S.)

History.—Before the Muslim invasions of northern India, Rajasthan was subject for the most part to powerful tribal dynasties, the most important of which were the Rathors ruling from Kannauj, the Chauhans of Ajmer, the Solankis of Anhilwara, the Sisodias of Mewar (Udaipur), and the Kachwaha clan in Jaipur. The origin of these Rajput tribes (*see* RAJPUT) is controversial, and historians refuse to accept their legendary pedigrees as recorded by James Tod in his *Annals and Antiquities of Rajasthan*, two volumes (first published in 1829–32). It is generally accepted that they can be divided into two main classes, the foreign and the indigenous. The foreign descent of certain clans is not improbable, as throughout Indian history foreigners have been accepted into the fold of Hinduism.

Until its incorporation in the Mauryan Empire the early history of Rajasthan is obscure. It is clear from the Junagadh rock inscription that Rudradaman (c. A.D. 130–150), the greatest of the western satraps (Saka governors; *see* SAKA), ruled over Maru or the desert country which may be roughly equated with this area, although the term is sometimes restricted to Marwar (Jodhpur). In the 4th century it formed part of the Gupta Empire. How much of it was annexed by Harsha (*q.v.*) in the first half of the

7th century is disputable. Disorder and political disintegration followed the death of Harsha. By the close of the 9th century, however, Rajasthan had been added to the extensive dominions of the Gurjara-Pratihara (*q.v.*) dynasty of Kannauj, which had become the paramount power in northern India. The constant internecine warfare between the various Rajput kingdoms facilitated the Muslim conquest of northern India. It was not, however, until the days of Mohammed of Ghor (*q.v.*) that the Rajput dynasties of the northern plains were finally overthrown. Driven from Delhi and Kannauj, they retired into Rajasthan, where they eventually built up a strong position which enabled them to resist the Muslim invaders; for, although there was constant warfare, it cannot be said that the sultans of Delhi (*see* DELHI, SULTANATE or) ever really subdued the Rajputs inside Rajasthan. The Rajputs nearest to Delhi were naturally the weakest because the eastern frontiers of Rajasthan were exposed to attack. Although unable to subdue the Rajputs, the sultans of Delhi appear to have realized the value of communications with the western coast, and the route between Delhi and Gujarat via Ajmer was usually open to imperial armies.

During this period the chief threat to the Rajputs was not from Delhi but from the independent Muslim kingdoms of Gujarat and Malwa. On the eve of Babur's invasion the outstanding feature of the history of northern India was the growth of Rajput power under Rana Sanga of Mewar, who extended his sway over the greater part of Rajasthan. His defeat by Babur at the Battle of Khanua in 1527 marks a turning point in Rajput history, for they never again attempted to recover their lost dominions on the plains and contented themselves with remaining on the defensive inside Rajasthan. After this battle the place of the Sisodias in Rajput politics was taken by the Rathors, the growth of whose power under Maldeo of Marwar was made possible by the weakness of Humayun.

Akbar's Rajput policy was based on conquest and conciliation. The fall of the Rajput strongholds of Chitor and Ranthambhor made him master of the greater part of Rajasthan, with the exception of Mewar which was not completely subdued until the reign of Jahangir. The reversal of Akbar's conciliatory policy produced the great Hindu reaction of Aurangzeb's reign when the Rajputs, Marathas, and other Hindu powers rose in revolt. But internal dissensions once more prevented the Rajputs from taking advantage of the decline of Mughal (Mogul) power and in the second half of the 18th century they proved no match for the Marathas who easily overran Rajasthan. At the same time Rajasthan was ravaged by predatory hordes of Pindaris and by the forces of Amir Khan, the Pathan freebooter. It was not until the beginning of the 19th century that the British, in the course of their struggle against the Marathas, entered into political relations with the Rajput states. Before the end of the year 1818 the states now incorporated in Rajasthan had been taken under British protection.

From the establishment of British paramountcy in India during the governor-generalship (1813-23) of the marquess of Hastings the history of Rajasthan was comparatively uneventful. Most of the rulers of Rajasthan remained loyal during the Indian mutiny of 1857-58, but in many places they were unable to prevent the troops and other inhabitants from taking part. In 1862, in accordance with the policy of the viceroy, Lord Charles Canning, the ruling chiefs were given *sanads* (charters) granting them the right of adoption in the event of the failure of natural heirs. Up to 1947 the Government of India was represented in Rajputana (as Rajasthan was then known) by a political officer styled agent to the governor-general, who was also chief commissioner of the small British province of Ajmer-Merwara. Under him were residents and political agents accredited to the various states.

In accordance with the policy of the Indian government after it attained independence in 1947 the former princely states of Rajputana (except for small areas transferred to neighbouring states) were formed into a constituent state under the name of Rajasthan. This was accomplished in four stages: (1) The short-lived Matsya Union of Alwar, Bharatpur, Dholpur, and Karauli was formed on March 18, 1948. (2) In April of 1948 the first

Rajasthan Union was formed which included Banswara, Bundi, Dungarpur, Jhalawar, Kishangarh, Kotah, Pratapgarh, Shahpura, Tonk, and Udaipur. (3) On March 30, 1949, the Greater Rajasthan Union came into being by the inclusion of the remaining states of Jaipur, Jodhpur, Bikaner, and Jaisalmer. (4) On May 15, 1949, the Matsya Union was incorporated in Greater Rajasthan and soon afterward part of Sirohi.

Ajmer State (formerly Ajmer-Merwara) was included in Rajasthan as the Ajmer district in 1956.

On the formation of Rajasthan the Rajput princes surrendered their powers to the central government. In exchange they were granted generous pensions and were allowed to keep their private property, including some of their palaces. The most famous and beautiful Rajput palace is on Lake Pichola in Udaipur.

(C. C. D.)

Population, Administration, and Social Conditions.—The state, although large, is sparsely populated; its population (1961) was 20,155,602. Besides Brahmans and Rajputs, other castes and tribes include Banyas, Jats, Gujars, Chamars, Meenas, Bhils, Malis or Kachhis, and Balais. Rajasthani with its various dialects is the chief language. (*See also* INDIA: *The People*; RAJASTHANI LANGUAGE.)

The state is divided into the 26 districts of Ajmer, Alwar, Banswara, Barmer, Bharatpur, Bhilwara, Bikaner, Bundi, Chittorgarh, Churu, Dungarpur, Ganganagar, Jaipur, Jaisalmer, Jalore, Jhalawar, Jhunjhunu, Jodhpur, Kotah, Nagaur, Pali, Sawai Madhopur, Sikar, Sirohi, Tonk, and Udaipur.

The chief cities and towns with their population (1961 census) are the following: Jaipur 403,444; Ajmer 231,240; Jodhpur 224,760; Bikaner 150,634; Kotah 120,345; Udaipur 111,139; Alwar 72,707; Ganganagar 63,854; Beawar 53,931; Sikar 50,636.

With only 23.7% of the male and 5.8% of the female population recorded as literate at the 1961 census, Rajasthan is one of the educationally backward states of India. In the early 1960s there were more than 22,000 educational institutions including Rajasthan University at Jaipur with 85 colleges affiliated to it. Primary education, though free throughout the state, was compulsory only in about 700 villages.

Besides about 500 hospitals and dispensaries, a number of health centres give free medical aid and health services to rural people. Approximately 24,000 factory workers and their families receive medical care through more than a dozen exclusive dispensaries in 10 industrial centres under a contributory health insurance scheme which covers risks of sickness, maternity, and employment injury. Welfare programs for tribal and backward classes comprise free education at all stages: scholarships, combined adult night school and social education centres, and rehabilitation of landless families. The state social welfare board organizes social welfare services for women and children in rural areas through crèches, elementary schools, adult literacy, social education, and craft training classes, and provides medical aid and maternity services.

(S. CH.; S. B. L. N.)

The Economy.—The chief towns were the capitals of former states, and their princely palaces remain among some of India's most beautiful buildings. Organization of the population was on a feudal basis; the standard of life depended largely on the energy, efficiency, and attitude of the reigning Rajput. Cities like Jaipur and Udaipur retain enough of their colourful past to attract a considerable tourist traffic; cottage industries and handicrafts survive and flourish there more than elsewhere in India. In the drier regions camel's hair is still used in the manufacture of blankets, carpets, cloths, etc.; elsewhere the wool of local sheep and goats provides the raw material. Rajasthan is a stronghold of the Jain religion, and this exercises considerable influence over local art. Agriculture as elsewhere in India is the dominant occupation, and in Rajasthan physical conditions are against the development of modern techniques. There is, however, a steady replacement of the poorer yielding crops by better. Whereas in about 1920 millets occupied 37% of the cropped area of the Rajput Upland as against 11% occupied by wheat, 8% by barley, and 3% by maize (corn), by the 1960s wheat, barley, and maize surpassed millets. Other noteworthy crops are pulses, sugarcane, cotton, and oil-

seeds. The important irrigation and power projects designed to benefit the state are the Bhakra-Nangal, Chambal, and Beas schemes (all undertaken jointly by the states of Rajasthan and Punjab), the Jawai and the Rajasthan Canal project. All these will help the lowlands in the northern part of the state.

The state has some important minerals. Four-fifths of India's gypsum comes from the southwest; salt is obtained both from the desert area and from Sambar Lake. There is a significant mica belt and a large production of limestone. Silver-lead-zinc ores have also been worked. From the limestone there is a considerable cement industry. Marble and sandstone are found in abundance. The other principal manufactures are textiles, glass, and sugar. The important cottage and small-scale industries are cotton weaving, enameling, and pottery, as well as work in ivory, brass, lac, and stone, and the manufacture of "tie and dye" fabrics or bandannas (from Hindi, *bandhana*, to tie), water bottles, wooden toys, embroidered shoes and leather bags, carpets, and agricultural tools and implements.

Rajasthan benefits from its position served by main routes from Bombay to Delhi and Indore to Ajmer by rail, though the main road passes to the south and east. The direct air route Karachi-Delhi crosses the state. There are airports at Jodhpur and Jaipur.

(C. C. D.)

RĀJASTHĀNĪ LANGUAGE is a group of Indo-Aryan dialects bordered by Western Hindī on the one side and by Gujarātī and Sindhī on the other—an area roughly that of Rāj-pūtānā and adjoining parts of central India.

Rājasthānī has many dialects which can be assigned to four main groups: northeastern, southern, western and east-central. The northeastern form, Mēwātī, approximates most closely Western Hindī. It is a transitional dialect and sometimes classified with Hindī. The southern, Mālvi, spoken in Mālwa and neighbouring areas, shares characteristics with Western Hindī to the east and with Gujarātī to the west. The western, Mārṇwārī, spoken in Mārṇwār and neighbouring districts, is geographically more extensive than all the other dialects combined. Jaipurī, the language of Jaipur, is the standard east-central dialect. It has affinities with Gujarātī, whereas Mārṇwārī resembles Sindhī. None of the Rājasthānī dialects is recognized in the Indian constitution. See also GUJARATI LANGUAGE; HINDUSTANI LANGUAGE.

Phonology.—With few exceptions, the Rājasthānī system agrees with other modern Indo-Aryan languages (*q.v.*). Long *ā* is sometimes pronounced like *au* in English "Paul," *ē* and *ai* like *a* in "hat" and *au* like *o* in "hot." In the west and south especially, *s* is replaced by *h*—in northern Gujarātī and in a number of the Bhil dialects. An original aspirate *h* and the aspiration of aspirated consonants are often lost; *ch* is replaced by *s*. In contrast with Western Hindī, Rājasthānī (like Gujarātī and Sindhī) retains the cerebrals *ḷ* and *ṇ*. Otherwise Rājasthānī shares a common ancestry with Gujarātī in Śaurasēnī Apabhraṃśa.

Morphology.—Rājasthānī has two genders: masculine and feminine. There are sporadic instances of the neuter, less in the subdialects toward the midland, more to the west and south to the borders of Gujarātī, which has three genders. A special agent form of noun is used instead of the oblique form with the postposition *ne*, though this construction is often encountered in Mēwātī and Mālvi.

A strong adjective agrees in gender, number and case with its noun; weak adjectives remain unchanged. The pronouns correspond generally with those of Hindī. In common with Gujarātī, Rājasthānī uses the inclusive pronoun *ap* "we." In conjugation a passive stem is formed with the suffix *ij*; Sindhī and Lahndā have a similar formation. The simple present indicative often functions as a subjunctive. The simple future stem is made by means of the suffix *s* (or *h*); a periphrastic future is formed by adding *gō*, *lō* or *lā* to the subjunctive, of which *gō* and *lō* agree in gender and number with the subject, while *lā* never changes. Compound tenses are formed from participles plus auxiliaries.

(See *Linguistic Survey of India*, vol. ix, pt. ii, 1908.)

The literature of Rāj-pūtānā, chiefly in manuscript form, includes a number of bardic chronicles. In Mārṇwār, premodern literature falls into two categories: *Dīngal* (composed in Mārṇwārī) and *Pīngal* (composed in Braj Bhāshā). Modern literary activity is sparse.

Chatterji, *Rājasthānī Bhāṣā* (1949); Sitārām Lāṣas, *Rājasthānī Vyākaraṇa* (1954).

(Et. B.)

RAJGARH, a town and district in the Bhopal division of Madhya Pradesh, India. The town, headquarters of the district, lies on the left bank of the Newaj River, 85 mi. (137 km.) NW of Bhopal by road. Pop. (1961) 9,095. It was founded about 1640 by Rawat Mohan Singh, who erected a defensive wall around it.

RAJGARH DISTRICT (area 2,383 sq.mi. [6,172 sq.km.]; pop. [1961] 516,871) includes chiefly the former princely states of Narsingharh and Rajgarh. The northern portion of the district is fairly hilly but the southern and eastern regions lie on the Malwa Plateau. About 45% of the total area is cultivated, growing wheat, jowar, and poppy. The Umat Rajputs ruled the princely states of Rajgarh and Narsingharh until, in the disturbances caused by the Maratha and Pindari inroads in the 18th century, Rajgarh became tributary to Sindhia. In 1818 it came under the suzerainty of the British-Indian government. It was absorbed in 1948 into Madhya Bharat, which was merged into Madhya Pradesh in 1956.

(S. M. A.)

RAJGIR HILLS, a range of hills in the south of the Patna district of Bihar, India. They form part of a range extending northeast for 40 mi. from the neighbourhood of Buddh Gaya; at one place they rise to 1,272 ft. (388 m.), but elsewhere they seldom exceed 1,000 ft. (300 m.). The hills in Patna district consist of two parallel ridges. In the valley between, south of the village of Rajgir, was built the old city of Rajagriha, "the royal residence." Legend ascribes it to Jarasandha, king of Magadha (south Bihar), who had his capital at Girivraja, "the city of hills." The outer fortifications can be traced on the crests of the hills for more than 25 mi.; they are 17½ ft. thick, built of massive undressed stones without mortar. These ruined walls are generally ascribed to the 6th century B.C. The remains of New Rajagriha, the reputed capital of Bimbisara (c. 520-490 B.C.), lie two-thirds of a mile north of the valley.

The Rajgir Hills are associated with the life of Buddha, who often taught there. Chhatagiri is the old Gridhrakuta, or Vulture's Peak, which was one of his favourite resorts. One of the towers on the Baibhar Hill (Vaibharagiri) has been identified as the Pippala stone house in which Buddha lived. The Sattapanni, the cave in which after his death the council of his disciples was held to record the tenets of the faith, has been identified with different sites on this hill and with the Sonbhandar cave at its foot; the latter is now believed to have been excavated by Jains in the 3rd or 4th century A.D. In the centre of the valley, excavations at the site known as Maniyar Math revealed a curious circular shrine associated with the worship of Mani-naga, a serpent deity, stated in the epic Mahabharata to reside at Rajgir. Rajgir is a place of pilgrimage. There are modern Jain temples on the hills around the valley. There are also hot springs in the valleys surrounded by Hindu shrines.

(F. R. A.)

RAJKOT, a town and district of Gujarat, India. The town, formerly the capital of the princely state of Rajkot and of Saurashtra, now the district headquarters, lies 125 mi. (201 km.) SW of Ahmedabad. Pop. (1961) 193,498. It is an important junction on the Western Railway with connections to most major

towns of Gujarat. There are three colleges (arts and science, law, and commerce) affiliated to Gujarat University. Other institutions include the Rajkumar College founded in 1870; the Jubilee Memorial Institute consisting of the Connaught Hall, Lang Library, and Watson Museum (1888); two hospitals; and two training colleges. Places of interest include the Lalpan and Randerda lakes and the Aji Dam.

RAJKOT DISTRICT has an area of 4,588 sq.mi. (11,883 sq.km.) and a population (1961) of 1,208,519. The bulk of the area constituted the former princely state of Rajkot, which was merged in 1948 into the new state of Saurashtra, formed after India became independent in 1947. In 1956 when Saurashtra was absorbed into Bombay State, Rajkot became a district. Bombay State was divided into Gujarat and Maharashtra in 1960.

The district is undulating, with a stony soil watered by several streams. The principal crops are grain, sugarcane, and cotton. The manufacture of cotton and woolen textiles is the main industry. (M. R. P.)

RAJMAHAL, a former capital of Bengal and now headquarters of a subdivision in the Santal Parganas district of Bihar, India, lies on the right bank of the Ganges, 55 mi. (89 km.) ESE of Bhagalpur. Pop. (1961) 6,801. It comprises a collection of mud huts interspersed with a few houses and some ruins of nobler buildings. Man Singh, Akbar's governor, chose Rajmahal for his capital in 1595-96 because of its strategic position and command of the Ganges, but in 1608 the seat of government was transferred to Dacca. It was again made the capital by the prince Shah Shuja in 1639, and was superseded a second time by Dacca 20 years later. The town is on a branch line of the Eastern Railway.

Rajmahal has given its name to a region of basaltic hills with an Archean basement. The hills comprise an area of 1,366 sq.mi. (3,538 sq.km.) and rise to 1,886 ft. (575 m.). They are inhabited by an aboriginal people known as Sauria Paharias ("hillmen"). The valleys are inhabited and cultivated by the Santals, another aboriginal people. (E. AH.)

RAJPRAMUKH (Hindi *raj[a]*, "prince" + *pramukh*, "chief official," "president," etc.), the title given to those Indian princes who, in 1948, were appointed in place of governors in certain constituent states of India where it was thought expedient to retain some of the traditional polity of princely jurisdiction and to employ the administrative ability of the princes. The states concerned were Hyderabad, Mysore, and five unions of former princely states—Madhya Bharat, the Patiala and East Punjab States Union, Rajasthan, Saurashtra, and Travancore-Cochin. The *rajpramukhs* of Hyderabad and Mysore were those princes recognized by the president of the republic as respectively *nizam* and *maharaja* of the two states; in the states unions the *rajpramukh* was elected for life by a council of the rulers of the covenanted states, and was usually the ruler of the most important of them. The *rajpramukh* was answerable to the state and republican legislatures and to the president of India, and retained none of the autocratic powers of the old princes; his position was rather that of a constitutional monarch. Kashmir, under dispute between India and Pakistan after the political partition of the subcontinent, was regarded in the 1950 Indian constitution as a *rajpramukh* state within the republic.

The office of *rajpramukh* was abolished when the States Reorganization Act came into force in 1956, most of the above-mentioned states being then absorbed into larger agglomerations. See Ministry of States, *White Paper on Indian States* (1950).

RAJPUT (Sanskrit *raja-putra*, "son of a king"; also known as *Thakur*, "lord"), a generic term for about 11,000,000 landowners (census of 1931) organized in patrilineal clans and located mainly in central and northern India, especially in former Rajputana. Regarding themselves as descendants or putative successors of the Kshatriya warrior-ruling class of ancient India, they vary greatly in status from princely lineages such as the Guhilot and Kachwaha down to lowly cultivators. Most authorities agree that successful claims to Rajput status frequently were made by groups that attained secular power; probably central Asian invaders as well as patrician lines of indigenous tribal peoples were absorbed in this way. There are numbers of Muslim Rajputs in the northwest,

and Rajputs generally have adopted the custom of *purdah*. Their ethos includes intense pride in ancestry, mettlesome regard for honour, and dedication to goals of power.

Rajputs are divided into four lines: Solar, Lunar, Fire-descended, and Snake. In imitation of the Brahmins some clans are grouped in exogamous *gotra* associated with a mythological seer (*rishi*). Rajputs seek hypergamous marriages (i.e., into a higher social group), and until recent times, rather than suffer the shame of unmarried or ill-married daughters, many who were unable to provide dowries for such marriages practised female infanticide.

Kingdoms founded in north and central India between the 8th and 12th centuries exemplified Rajput rule. Learning and commerce flourished; chivalric warfare was a dominant pattern, and quixotic bravery was encouraged by courtly bards. During the years of Islamic supremacy the centre of Rajput influence shifted to Rajputana, and petty Rajput kingdoms there were among the main obstacles to the complete Muslim domination of Hindu India. Until their reorganization as part of the republic (1948) they preserved much of their ancient structure. Patriarchal rather than feudal, they derived most land rights, from those of sub-chiefs to poorest farmers, from blood relationship to the sovereign. Many remnants of former Rajput clan-kingdoms are found in the Punjab and along the Gangetic plain. In recent times Rajputs provided an important segment of India's fighting forces. See also RAJASTHAN.

See James Tod, *Annals and Antiquities of Rajast'han* (1829-32; Oxford ed., 1920); Daniel Thorner, "Feudalism in India," in Rushton Coulborn (ed.), *Feudalism in History* (1956). (J. T. H.)

RAJPUTANA (literally "the land of the Rajputs"), a group of princely states lying toward the northwest of India which, under the British regime, formed an agency. It was so called because the ruling princes were almost all Rajputs (see RAJPUT). The area of the whole was 132,559 sq.mi. (343,328 sq.km.) and the population, mainly of Hindus speaking Rajasthani and Hindi, was 13,670,208 at the 1941 census. There were 23 states, 1 chiefship, and 1 estate. The whole formed a compact block occupying hilly and plateau country between the plains of northern India and the main plateau of peninsular India. Running roughly through the centre from southwest to northeast was the Aravalli Range, to the northwest of which was the Thar Desert (q.v.). In the midst of the group of states was the tiny British-Indian province of Ajmer-Merwara of 2,400 sq.mi. (6,216 sq.km.) and 583,693 people in 1941. The largest states were Jodhpur, Jaisalmer, Bikaner, Jaipur, and Udaipur. Others included Alwar, Banswara, Kotah, Bundi, Tonk, and Kishangarh. With the coming of independence in 1947 a union of states began, until in due course the main group of states was consolidated, together with Ajmer-Merwara, as the new state of Rajasthan. Some territory in the southeast is now part of Madhya Pradesh and some in the southwest was transferred to Bombay (now Gujarat). See also RAJASTHAN: History. (L. D. S.)

RAJSHAHI (formerly RAMPUR BOALIA), a town, district, and division of East Pakistan. The town, headquarters of the district and division, lies on the Ganges (sometimes there called the Padma) River, 120 mi. (193 km.) WNW of Dacca. It stretches 5-6 mi. along the river, with a west-east metaled road forming the main axis. Pop. (1961) 56,885. The principal buildings include the Circuit House, Jinnah Hall, Sadr Hospital, Varendra Research Museum, and the impressive Bara Kothi of Dutch origin, now housing part of Rajshahi University (established in 1953), which has four affiliated colleges. In the 1960s the main university buildings were being constructed beside the campus, about 3 mi. E of the town. The town has oil mills and sawmills, a match factory, and a silk institute.

RAJSHAHI DISTRICT (area 3,654 sq.mi. [9,464 sq.km.]; pop. [1961] 2,810,964) is believed to have originally formed part of the old kingdom of Pundra or Paundravardhana, the country of the Pods, whose capital was at Mahasthan. Under the Sena kings in the 12th century Mahasthan was known as the Barendra Bhumii, a name that still survives in the Barind tract. The district contains a number of historical sites. Rice is the chief crop followed by jute and pulses. Sericulture is an old industry accounting for

almost the entire silk output of East Pakistan. Other cottage industries include weaving, metal and wood working, and pottery.

RAJSHAHI DIVISION comprises the districts of Dinajpur, Rangpur, Bogra, Pabna, and Rajshahi, and forms a compact block in the northwest of East Pakistan, bordered southwest and south by the Ganges and east by the Jamuna. Area 13,347 sq.mi. (34,569 sq.km.). Pop. (1961) 11,850,089. Between the silts (pali) of the riverine lands and the red soils (khiar) of the midwest, the soils are mostly sandy loams. The eastern part lies in the main jute belt of East Pakistan and produces *aus* (autumn) rice. The *aman* (winter) rice is almost a universal crop. Wheat and tobacco are grown in the northeast. (K. S. Ad.)

RÁKÓCZY, the name of a noble Magyar family, settled from early times in the county of Zemplén.

ZSIGMOND RÁKÓCZY (1544–1608) was one of the foremost supporters of István Bocskay (*q.v.*) in his rising against Catholic encroachment in northern Hungary, and succeeded him for a brief period in 1607 as prince of Transylvania, resigning the throne in 1608 in favour of Gábor Báthory. He died in the same year on Dec. 5.

GYÖRGY RÁKÓCZY I (1593–1648), born on June 8, 1593, the youngest son of Zsigmond, was also a staunch Protestant. He took a leading part in the rebellion of Gabriel (Gábor) Bethlen (*q.v.*), and after Bethlen's death was elected prince of Transylvania by the diet of Segesvár (Sighişoara) on Nov. 26, 1630. Following Bethlen's national Hungarian policy, he declared war in alliance with Sweden against the Holy Roman emperor Ferdinand III in 1644, on behalf of the oppressed Protestants of northern Hungary. By the Peace of Linz (Dec. 16, 1645) he secured the confirmation of Hungarian religious liberties. His capital Gyula Fehérvár (Alba Iulia) became a great Protestant centre. Early in July 1648, after the death of King Wladyslaw IV Vasa, Rákóczy put forward his second surviving son, **ZSIGMOND** (1622–1652), as candidate for the Polish throne. When this candidature was rejected, he made advances to the dissident Polish Calvinists led by Prince Janusz Radziwill, but he died at Sárospatak on Oct. 11, 1648.

GYÖRGY RÁKÓCZY II (1621–1660), born at Sárospatak on Jan. 30, 1621, was the eldest surviving son of György I and Zsuzsanna Lorántffy. In 1643 he married Zsófia Báthory, who embraced Calvinism for the purpose. Succeeding his father as prince of Transylvania in 1648, he sought like him alliances with the neighbouring hospodars (lords) of Moldavia and Walachia. He joined Charles X Gustavus of Sweden in attacking Poland in 1656, hoping to be elected king of that country. He undertook this expedition in defiance of the Turks, to whom Transylvania still owed tribute. Rákóczy was forced to retreat on humiliating terms. He was deposed by the Transylvanian diet on Turkish orders in 1657, but was reinstated a year later, whereupon the Turks invaded Transylvania in force. Rákóczy died at Nagyvárad (Oradea) on June 7, 1660, of wounds received at the Battle of Gyalu (Gilău) in May.

FERENC RÁKÓCZY I (1645–1676), born on Feb. 24, 1645, was the son of György II. His mother, disregarding his father's last wishes, in 1662 procured his conversion to Catholicism, to which she had herself reverted. Though he never succeeded his father, he kept a splendid court on the family estates at Sárospatak and Makovica. In March 1666 he married Ilona, daughter of Count Péter Zrinyi (Zrinski), ban of Croatia; and in 1670 he joined Zrinyi and Duke Kristó Frankopan in a conspiracy aiming at the liberation of Hungary and Croatia from Habsburg domination. Their insurrection was defeated, and Zrinyi and Frankopan were beheaded in 1671, but Rákóczy escaped death through the influence of his mother with the Jesuits, on the payment of a ransom. He died on July 8, 1676, at Makovica.

FERENC RÁKÓCZY II (1676–1735) was born at Borsi, in Zemplén, on March 27, 1676, less than 15 weeks before the death of his father Ferenc Rákóczy I. He was brought up, together with his sister Juliana, by his mother Ilona Zrinyi in an atmosphere of fervent Magyar patriotism. Her marriage in 1682 to Imre Thököly, leader of the Hungarian Protestants and organizer, with Turkish assistance, of abortive anti-Habsburg risings, did much to dissipate the family fortune. Defeated, Thököly went into

exile, leaving his wife to organize alone the defense of Munkács (Mukachevo, in Transcarpathian Ukraine). After the surrender of Munkács (1688), the boy Ferenc, torn from his mother and sister, was taken to Vienna to be brought up in Austrian ways. His appointed master, Cardinal Leopold Kollonich (1631–1707),

a man of Croatian descent and an adversary of Magyar nationalism, put him in the Jesuit College of Neuhaus (Jindřichuv Hradec, in Bohemia); but Ferenc remained an ardent Hungarian. His emancipation from the cardinal was helped by his sister's marriage to a Belgian nobleman in the Austrian service, Ferdinand d'Aspremont-Linden, count of Reckheim. The couple encouraged Ferenc in his marriage to Charlotte Amelia of Hesse-Rheinfels, solemnized in 1694. Rákóczy settled on his Hungarian estates. His birth, wealth, and brilliant personal qualities made him the natural leader of the Magyar nation, a role in which he was encouraged by other magnates. On the eve of the War of the Spanish Succession (*q.v.*) they sought help for the Hungarian cause from Louis XIV of France. Their intermediary betrayed his trust, and Rákóczy was arrested and imprisoned at Wiener Neustadt, where his grandfather Péter Zrinyi had met his fate. Escaping death with his wife's help by leaving his cell in disguise, he took refuge in Poland, where he remained for two years. In 1703 he returned to Hungary, putting himself at the head of the peasant revolt known as the Kuruc rising. He had some initial success, but the Magyar gentry stood aloof, and the Anglo-Austrian victory at Blenheim (*q.v.*) in 1704 destroyed hopes of help from France. On June 13, 1704, the Kuruc army of 7,000 was routed by the emperor Leopold I's forces at Nagyszombat (Trnava, Slovakia). Permanent success in the open field was impossible, yet Rákóczy drilled his little army into some degree of efficiency and continued the fight against the emperor.

Meanwhile the Transylvanians were looking to Rákóczy to restore their independence: he was elected prince on July 6, 1704, and he set up a council of state of 24 members. In 1705 he was made dux (duke or leader) of a Hungarian confederation. His efforts to secure toleration for his Calvinist followers alienated the Holy See, and negotiations with the emperor during 1705 came to nothing, the latter refusing to acknowledge the independence of Transylvania. France would not recognize the rebels officially unless they formally proclaimed the deposition of the Habsburgs, a desperate measure actually adopted by the diet of Ónod on June 13, 1707.

In spite of this Louis XIV sent no effective help. Rákóczy's efforts to secure the Russian tsar Peter I's help against Austria failed; his peasant armies suffered further heavy defeats; and finally he left his country forever on Feb. 21, 1711, a few months before the signing, on May 1, of the Peace of Szatmár (Satu Mare). After two years in Poland, he took refuge in France in 1713 on Louis XIV's invitation.

In 1717 Rákóczy accepted a Turkish invitation to help organize an army in Turkey against the Austrians (he was to have a new principality as his reward); but before he reached Istanbul Sultan Ahmed III concluded peace and had no use for his services. Exiled in 1719 to Rodosto (Tekirdag), near Istanbul, Rákóczy remained there until his death on April 8, 1735. His remains were solemnly transferred to Hungary in 1906.

His two sons, **JÓZSEF** (1700–1738) and **GYÖRGY** (1701–1756), lacked character. József was recognized by the Turkish sultan as prince of Transylvania in 1737 but died the following year.

See *Histoire des Révolutions de Hongrie*, containing memoirs of Ferenc Rákóczy II (1739); Émile Horn, *François Rákóczi II* (1906). (B. Br.; X.)

RÁKOSI, MÁTYÁS (1892–1963), Communist ruler of Hungary from 1945 to 1956, was born at Ada (now in Yugoslavia), on March 14, 1892, of Jewish parentage; earlier versions of his family name were Rabinovics and Roth. His precocity and talent for languages enabled Rákosi to enjoy a good education, culminating in the Oriental Academy at Budapest, and to travel in Germany and England. He had early joined the Social Democratic Party. Taken prisoner on the Russian front in 1915, he was indoctrinated and sent back to Hungary in 1918. From March to August 1919 he was commissar for socialist production in the Communist government of Béla Kun (*q.v.*), on the fall of which he escaped to Russia. He rose quickly in the Communist hierarchy and was entrusted with various missions abroad. In 1925, in an attempt to refound a Hungarian Communist Party, he was apprehended by the Hungarian police; and in 1927, after a trial in which he defended himself with great courage and fluency, he was sentenced to eight-and-a-half years' imprisonment from the date of his arrest. On the expiration of this he was rearrested and sentenced in 1934 to life imprisonment on new charges, but in November 1940 he was allowed to go to Moscow in exchange for Hungarian colours captured by the Russians in 1848–49. He returned to Hungary with the Soviet Army at the end of 1944 and became secretary of the reconstructed Hungarian Workers (Communist) Party. In supreme control, he served as deputy prime minister from 1945 and as prime minister from Aug. 14, 1952, to July 2, 1953, when, after Stalin's death, he was partially demoted in favour of Imre Nagy. He remained first secretary of the party, however, and in April 1955 he reasserted his power by removing Nagy from the premiership; but on July 18, 1956, he was forced to resign by N. S. Khrushchev in order to placate Marshal Tito, whom Rákosi had offended. His systematic sacrifice of the interests of Hungary to those of the U.S.S.R., coupled with his unendearing personal qualities, had made him generally loathed in Hungary, and when revolution broke out in October 1956 he fled again to the U.S.S.R. His death in Moscow was reported on Aug. 15, 1963.

(C. A. M.)

RAKOVSKI, GEORGI SAVA (1821–1867), Bulgarian revolutionary leader and writer, one of the early and most influential promoters of the Bulgars' struggle for independence, was born at Kotel, near Sliven, of a well-to-do family. He received a good education in Istanbul and in France, but while still at school in Turkey became involved in political conspiracy, which was to be his main activity for the rest of his life. During the Crimean War, as an employee of the Turkish war office, he was secretly organizing armed revolt in Bulgaria. Found out and sentenced to death, he escaped abroad and began writing and publishing political propaganda in Serbia, Rumania, and Russia. From 1861 he concentrated on organizing the revolution in Bulgaria, recruiting and equipping bands of volunteers to be sent into Bulgaria or to help the Serbs in their armed clashes with the Turks (1862 and 1867). After several failures, his tactics of piecemeal risings had to be abandoned for coordinated revolt by the mass of the population, but his leadership gave the first real impetus to Bulgarian resistance. The literary merits of his writing are open to doubt, but what he wrote had a widespread effect on the minds of younger Bulgarians on the eve of their country's emergence as an independent state. He died in Bucharest on Oct. 20 (new style; 8, old style), 1867. His memoirs were published by M. Arnaudov in 1925.

(N. I. M.)

RAKOVSKI, KHRISTIAN GEORGIEVICH (1873–?), Soviet Communist leader and diplomat who was a victim of Stalin's purges, was born on Aug. 13, 1873, at Kotel in Bulgaria. His father's home in the Dobruja passed under Rumanian rule in 1878, and the family became Rumanian, but the Bulgarian and revolutionary traditions inherited from his grandfather Georgi Sava Rakovski (*q.v.*) were strong in Khristian. Excluded from Sofia University because of his socialist activities (1890), he went to Geneva and then to Montpellier, where he graduated as a doctor of medicine. Returning to Bulgaria, he resumed his subversive activities. In 1900 he served as an officer in the Rumanian Army, but in 1907, during the peasant riots, he was expelled from Rumania, where his civil rights were not restored till 1912. Many of

his books were published in Russia under the pen name Insarov.

After Rumania's entry into World War I, Rakovski was arrested. Taken to Iași, he was released there by the Russians on May 1, 1917. When the Communists came to power in Russia (November 1917) he became a member of the All-Russian Central Executive Committee; and in 1919 he was appointed to the Central Committee of the Communist Party. Having led the delegation sent to negotiate peace with the Ukrainian central *rada* (council), he was made chairman of the Council of People's Commissars of the Ukraine, also in 1919. He was a member of the Soviet delegation at the conference of Genoa (1922), Soviet *chargé d'affaires* in London (1923–25), and Soviet ambassador to France (1926–27), but his support of Trotsky led, in 1927, to his being expelled from the Communist Party and exiled to Stalingrad. One of the last Trotskyists to recant, he was readmitted in 1935 and was a departmental chief in the People's Commissariat of Health until 1937, when he was dismissed. He was among the 21 members of the "Right-Trotskyist bloc" arrested on Stalin's orders in February 1938. His trial (March 2–13) ended with his being sentenced to 20 years' imprisonment, and Rakovski must be presumed to have died in a concentration camp.

RALEGH (RALEIGH), SIR WALTER (c. 1554–1618), English soldier, seaman, courtier, author, and explorer, the first to settle colonists in Virginia and to open up Guiana to English enterprise, was the brilliant favourite of Elizabeth I. A strong

advocate of the application of naval pressure to counter the threat from Spain, he was concerned in several privateering ventures, as well as in large-scale expeditions to Cádiz and the Azores. Even more success, he believed, would follow the establishment of land bases from which to operate in the New World. Among many prose works, those printed in his lifetime are still the best known. *A Report of the Truth of the Fight About the Isles of Azores* is propaganda for the war at sea. *The Discoverie of Guiana* describes his exploration of the Orinoco in search of a secret empire of the Incas, with which he hoped to rival Spanish conquests in South America. *The History of the World*, which solaced a long imprisonment under James I, warned princes that their crimes do not go unpunished, and summed up the littleness of man.

His occasional verse has an individual note of gravity and disillusion.

He was a younger son of Sir Walter Raleigh (d. 1581), of Fardell in Devon, by his third wife Katherine Gilbert, daughter of Philip Champemown. He was born in 1554 (or possibly two years earlier) at Hayes Barton near Budleigh Salterton (Devon). In October 1569 he was serving the Huguenot cause in France, where he claims to have been at the Battle of Moncontour. In 1572 his name appears in a list of members of Oriel College, Oxford, and in 1575 on the registers of the Middle Temple. In 1577 he described himself as "de curia," a member of the court. In 1578 he was at sea with his half brother Sir Humphrey Gilbert, destroying Spanish shipping. He went to Ireland in 1580, and fought with as much ruthlessness as gallantry against the rebels in Munster. He was one of the officers of the day when the whole garrison of Smerwick, County Kerry, was executed on the orders of the deputy, Lord Grey of Wilton. Raleigh was openly critical of the dilatory conduct of the war and it may have been his plausibly urged schemes for the quick subjection of Ireland which first brought him to the notice of Elizabeth I. He returned to England in December 1581

SIR WALTER RALEGH, ENGRAVING BY SIMON PASS, FROM THE TITLE PAGE OF THE 1614 EDITION OF RALEGH'S "THE HISTORY OF THE WORLD"

and by 1582 was the reigning favourite. If ever he spread his cloak in the mud for the queen to pass over, as tradition alleges, this was the time. He was notorious for his pride and personal display. In 1583 he received a lease of part of Durham house in the Strand, London, which he occupied till James I reclaimed it for the bishop of Durham in 1603. His monopoly of wine licences (1583), and of the export of broadcloth (1584), brought large receipts at the cost of much unpopularity. He was challenged as a monopolist in the Parliament of 1601. In 1585 he was knighted. After this year he regularly wrote his name Raleigh and did not himself use the form which later became common. The wardenship of the stannaries (1585) won him the loyalty of the Cornish tanners whom he helped through years of depression. As lieutenant of Cornwall he saw to the mustering of soldiers, which seems to have been his chief duty in the Armada year (1588). As vice-admiral of Devon and Cornwall he kept order in the naval prize courts. He had little to learn about licensed depredation at sea.

His Irish service was rewarded by vast estates in Munster, where his name is associated with Youghal, Cork, and Lismore. The land proved more trouble than it was worth, and in 1602 he sold it to Richard Boyle, afterward 1st earl of Cork. In 1587 he received the forfeited estates of the conspirator Anthony Babington, and in the same year was made captain of the queen's guard. This was the highest position he achieved. He would dearly have loved to be a privy counselor. The nature of his ascendancy with the queen kept him in attendance on her at court, and his grand schemes tended to languish for want of his personal participation. In 1591 she prevented his joining a naval expedition against Spain, in which his cousin, Sir Richard Grenville, was lost with the "Revenge." He commemorated the event in an inflammatory pamphlet, *A Report of the Truth of the Fight About the Isles of Azores* (1591), generally known by its running headline as *The Last Fight of the Revenge*. Though he never himself set foot in North America, he spent much pains and money upon establishing a colony near Roanoke Island, on what is now the coast of North Carolina, naming the country Virginia in honour of the queen (see NORTH CAROLINA). His first expedition sailed in 1584, after he had taken over Sir Humphrey Gilbert's charter for the discovering of "remote heathen and barbarous lands." The colony met with a succession of disasters and in 1589 he transferred most of his responsibilities to a syndicate of merchants. He encouraged the use of tobacco and, it is said, of potatoes, but the popular belief that he imported the potato from Virginia overlooks the fact that it is not indigenous there. From 1584 onward he served fairly regularly in Parliament, urging increased expenditure on defense, but not to the detriment of the poorer taxpayer, who always had his sympathy. He was opposed to heresy hunting. When more stringent laws were proposed against persons suspected to be religious sectaries he declared it intolerable that it should be in the power of juries to "judge men's intentions" and "what another meant."

Raleigh had a rival at court in the young Robert Devereux, 2nd earl of Essex, beside whom he inevitably had the air of a parvenu. His position was always precarious. During a passing period of disfavour, in 1589, he returned to Ireland, where he visited Edmund Spenser at Kilcolman Castle, County Cork. They exchanged verses. Raleigh, who cultivated poetry as a social art and a private recreation, read Spenser a plaintive poem addressed to the queen under the name of Cynthia. An autograph fragment preserved among the Cecil Papers is probably a continuation of the poem Spenser heard. He introduced Spenser at court and encouraged him to publish the first three books of *The Faerie Queene* (1590). In 1592 he suffered a serious setback. He had actually sailed in command of a naval expedition to seize the Spanish treasure fleet when he was recalled on account of a secret marriage with one of the queen's maids of honour. She was Elizabeth, daughter of Sir Nicholas Throckmorton, who made him a loyal and loving wife. The marriage cannot be precisely dated. The discovery in the early 1960s of a diary kept by Lady Raleigh's brother (see A. L. Rowse, *Raleigh and the Throckmortons*, 1962) indicates that it was an accomplished fact some months before the queen, always resentful when a favourite betrayed her platonic favours, sent the pair to the Tower in August 1592. The diarist

first heard of it in November 1591. On March 29, 1592, he records the birth of a son, Damarey, who must be presumed to have died in infancy. In 1593 there was another son, Walter, and in the winter of 1604-05 a third son, Carew. While the court storm raged, Raleigh's squadron at sea fell in with one of the richest prizes ever taken by English privateers, the Portuguese carrack "Madre de Dios." Raleigh was sent to Plymouth (September) as the only man who could keep order among the jubilant sailors and unravel the complicated finances of the voyage. He bought his release by making over the bulk of his profits to the queen.

Raleigh now retired to his newly acquired estate of Sherborne, in Dorset, which in January 1592 with the queen's help had been alienated from the see of Salisbury. In 1593 local gossip fixed upon him a charge of atheism, but failed to substantiate it before an ecclesiastical commission in 1594. In 1592 the Jesuit pamphleteer Robert Parsons had complained of his "School of Atheism," and his name was coupled with that of Christopher Marlowe. He was a bold thinker and an indiscreet talker, interested in scientific studies, especially in mathematics as an aid to navigation, and he read skeptical philosophy, but he was not an atheist in the modern sense. Some scholars, interpreting the obscure phrase "Schoole of night" in *Love's Labour's Lost* (Act IV, scene iii, line 272) as the equivalent of "School of Atheism," have read the play as a satire upon Raleigh and his friends.

Free to follow his bent at last, in 1595 Raleigh sailed for the Orinoco, with the aim of driving a wedge into the heart of the gold-bearing empire of Spain. His *Discoverie of Guiana* (1596) gained the projected colony little practical support, but it had many readers and implanted in English minds the dream of El Dorado. In 1596 he went with Essex to attack Cádiz, commanding the "Warspite," in which he was wounded. He described and defended his part in the sea fight (*Works*, 1829, volume viii). In 1597 he was received again at court. He joined Essex as rear admiral on the Islands voyage (1597), an expedition to the Azores, and conducted a successful land operation in his general's absence, for which he narrowly escaped a court-martial. In 1600 he became governor of Jersey, where he improved the fortifications, encouraged trade, and instituted a register of landed property. Essex by this time was losing ground and he and his adherents grew bitterly hostile to Raleigh, to the point of attempting his life in the rebellion of 1601.

The accession of James I in 1603 proved Raleigh's downfall. An apparent friend, Robert Cecil, later earl of Salisbury, and an open enemy, Lord Henry Howard (created earl of Northampton in 1604), had implanted a deep suspicion of him in the mind of the Scottish king. He was rebuffed and stripped of money and offices. Before long he faced a charge of treason. He was said to be involved in a plot to make peace with Spain, extort toleration for Roman Catholics, and put James's cousin Arabella Stuart on the throne. After defending himself magnificently, he was convicted upon the written evidence of one of the plotters, Henry Brooke, Lord Cobham, with whom he had been on intimate terms. It was possible to argue that he could not be totally ignorant of anything to which Cobham was committed. Even contemporaries, little disposed to favour him, thought the trial (November 1603) cruelly unjust, though the attorney general, Sir Edward Coke, who refused to let Cobham testify in court, observed the law as it was then, for a brief period, interpreted. The conduct of Raleigh's life does not suggest that he would support Spain. He was relieved at the last moment and confined for 13 years to the Tower, with varying degrees of strictness. He fought hard for a pardon, and to preserve Sherborne. In 1602 he had conveyed it in trust for his wife and child, but a clerical error rendered the deed invalid, and in 1609 the land went to the king's favourite, Robert Carr (later earl of Somerset). There was some compensation, more nominal than real, which seemed wholly inadequate to the Raleigh family. Raleigh occupied himself with chemical experiments, assaying of metals, and with the composition of his *History of the World*. The first and only volume to be completed was published in 1614. It begins with the creation and extends to the 1st century B.C., demonstrating that the world is the theatre of God's judgments. It was very highly esteemed in the 17th century and offers some

fine passages of English prose, of great rhythmical beauty and solemnity.

Raleigh's hopes of release faded in 1612, with the death of King James's eldest son, Prince Henry, who had fallen under his spell. A medicinal cordial of his compounding was administered to the prince *in extremis*, at the request of his mother, Queen Anne. It became famous but it is doubtful whether it had any real medical value. Queen Anne continued friendly and so did the anti-Spanish secretary of state, Sir Ralph Winwood. In 1616, with the help of a new favourite, George Villiers (afterward duke of Buckingham), he was released to lead an expedition to Guiana, whence he promised to bring gold without giving just cause of offense to Spain. All depended on the interpretation of "just cause," since Spain was certain to be offended. He may well have had designs on Spanish shipping, as well as secret knowledge of a gold mine. He made private overtures to France, hoping for a refuge in French ports, and was heard to ask openly, in his dangerous, jesting way, "Did you ever hear of any that was counted a pirate for taking millions?" He was gambling on success, and in the event failed miserably. The exploring party was led by his tried lieutenant, Lawrence Keymis, who had been with him in Guiana before. Raleigh himself stayed at Trinidad recovering from a tropical fever. Keymis, in defiance of stringent orders, attacked and burned the frontier town of San Thomé, erected in 1596 to guard the approach to Guiana. Spanish reports allege that the attack was a feint, contrived between the English and a faction within the town, who were anxious to trade without appearing to fraternize. In the event it turned to earnest. Raleigh's son Walter was killed in the assault. Keymis, upon whom the main responsibility must be laid, committed suicide before they started on the homeward voyage. He had excused the attack on the town by asserting that he stumbled upon it unexpectedly, 20 mi. from its previous site. Spanish records make it plain that he was lying when he said it had been moved. Raleigh repeated the story, apparently in good faith, arguing eloquently, before and after his arrest, that Guiana was English territory. (See his *Apology for the Voyage to Guiana*, *Works*, 1829, volume viii.) At last he listened to the friends who urged flight. An abortive attempt to escape to France was foiled by his own kinsman, Sir Lewis Stukely. He was beheaded on Oct. 29, 1618, in Old Palace Yard, Westminster. His wife and son survived him. Since he had sailed without a pardon, his conviction was still upon the old charge of conspiring with Spain. His behaviour on the scaffold won him sympathy and admiration, and public opinion, increasingly hostile to Spain and the Stuarts, soon made a hero of him.

He left a number of prose pamphlets vigorously written on a wide selection of subjects, ranging from philosophy, politics, and economics to practical shipbuilding. Many of them were printed, with more enthusiasm than discrimination, in the mid-17th century. The canon is still unsure. He had to an unusual degree the renaissance gentleman's aversion to the publication of his poetry. Since much of it was a way of courting the queen it may be said to have been intended for an audience of one. With the exception of the autograph fragments at Hatfield house, it has had to be collected from anthologies, where it is anonymous, and from commonplace books of doubtful authority.

Raleigh's peculiar power to dazzle, excite, and persuade is still active in his writings. Sober historians, after discounting the dazzle, tend to dismiss him as a not too scrupulous adventurer who had little influence upon events. A succession of biographers has found his personality both fascinating and elusive. He was a great mythmaker, whose greatest myth was of a golden city and an imaginary empire of the Incas in Guiana. Under the Commonwealth he himself became a legend; no longer the atheist, the monopolist, the overdressed arrogant favourite of Elizabeth's days, nor the malcontent, who schemed against King James, but a wise and farsighted statesman, who championed England against the might of Spain, extended its territory overseas, asserted God's providence in the history of the world, and fell a victim to Stuart tyranny. The truth lies somewhere among these conflicting pictures. His vaulting imagination, which could envisage both North and South America as English dominions, was backed by practical

ability and a capacity for hard work, but some discrepancy between the imagination and the deed made him less effective than his great gifts promised.

BIBLIOGRAPHY.—*Editions, etc.*: The first, and only, complete collection of the works is that in 8 vol. (1829); vol. i includes lives of Raleigh by W. Oldys and T. Birch. The first reliable collections of his scattered verse were included in A. J. Hannah, *Poems by Sir Henry Wotton, Sir Walter Raleigh and Others* (1845), and, more fully, in *The Courtly Poets from Raleigh to Montrose* (1870). The standard edition is by Agnes Latham, *The Poems of Sir Walter Raleigh* (1929; rev. ed. for Muses' Library, 1951). Editions of separate works include *The Discoverie of Guiana*, by Sir R. H. Schomburgk (1848), and by V. T. Harlow (1928); *Instructions to His Sonne, for the Roanoke Island Historical Association* (1939) and, with Lord Burghley's *Certaine Precepts* and Francis Osborn's *Advice to a Son*, by C. B. Wright for the Folger Shakespeare Library (1962). Selections from his prose were ed. by G. E. Hadow (1917). See also T. N. Brushfield, *A Bibliography of Sir Walter Raleigh*, 2nd ed. (1908).

Biography: For early notices see especially R. Naunton, *Fragmenta Regalia* (1641; rev. ed., 1653, ed. by E. Arber, 1870); J. Aubrey, *Brief Lives*, ed. by O. L. Dick (1949). The biography by Oldys in vol. i of the *Works* was written for the 1736 ed. of *The History of the World*. E. Edwards' well-documented *Life of Sir Walter Raleigh*, 2 vol. (1868), remains a standard work: vol. ii consists of a fairly complete collection of Raleigh's letters. Other biographies include those by W. Stebbing (1891; reprinted with bibliography, 1899); M. A. S. Hume (1879), using Spanish documents; M. Waldman, 2nd ed. (1943); E. Thompson (1935); W. M. Wallace (1959). See also S. R. Gardiner, *History of England . . . 1603-42*, 10 vol. (1883-84).

Special Aspects: C. H. Firth, *The History of the World*, a British Academy lecture (1918; publ. 1919), reprinted in *Essays, Historical and Literary* (1938); A. Acheson, *Shakespeare and the Rival Poet* (1903), which first propounded the supposed satire on Raleigh in *Love's Labour's Lost*; L. Cust, "The Portraits of Sir Walter Raleigh," in *The Eighth Volume of the Walpole Society* (1920); N. Kempner, *Raleighs Staatstheoretische Schriften: die Einführung des Machiavellismus in England* (1928); V. T. Harlow, *Raleigh's Last Voyage* (1932); D. B. Quinn, *Raleigh and the British Empire* (1947) and *The Roanoke Voyages, 1584-1590*, 2 vol. (1955), documents edited for the Hakluyt Society; J. Bruce Williamson, *Sir Walter Raleigh and His Trial* (1936); P. Edwards, *Sir Walter Raleigh* (1953), which deals with Raleigh as a literary figure; M. C. Bradbrook, *The School of Night: a Study in the Literary Relationships of Raleigh* (1936); E. A. Strathmann, *Sir Walter Raleigh: a Study in Elizabethan Skepticism* (1951); W. F. Oakshott, *The Queen and the Poet* (1960); A. L. Rowse, *Raleigh and the Throckmorton* (1962); P. Lefranc, "La Date du mariage de Sir Walter Raleigh," *Études Anglaises*, vol. ix (1956); A. M. C. Latham, "A Birth-Date for Sir Walter Raleigh," *Études Anglaises*, vol. ix (1956); C. S. Emden, *Oriel Papers* (1948); A. M. C. Latham, "Sir Walter Raleigh's Gold Mine," *Essays and Studies by Members of the English Association*, new series, vol. iv (1951). (A. M. C. L.)

RALEIGH, SIR WALTER ALEXANDER (1861-1922), Scottish man of letters and critic, a prominent figure in the Oxford of his time, was born in London on Sept. 5, 1861. He was educated at University College, London, and King's College, Cambridge. He held the chair of modern literature at Liverpool (1889-1900), and of English at Glasgow, and was appointed Oxford's first professor of English literature in 1904. Raleigh was a brilliant and stimulating talker and lecturer, and became the centre of the Oxford English school, which had only been established in 1894. His books (*Style*, 1897; *Wordsworth*, 1903; *Shakespeare*, 1907; *Six Essays on Johnson*, 1910; etc.) are the essays not of an exact scholar but of an urbane critic, sensitive without eccentricity, synthetic rather than analytic. He also wrote volume i of the official history *The War in the Air* (1922). He was knighted in 1911, and died at Oxford on May 13, 1922.

See his *Letters, 1879-1922*, ed. by his wife, with preface by D. Nichol Smith, 2 vol. (1926; enlarged 1928). (M. Kl.)

RALEIGH, the capital of North Carolina, U.S., located 23 mi. (37 km.) SE of Durham, has four major characteristics: politics, education, trade, and manufacturing. Politically, as the state capital (and the seat of Wake County), the city is much like other state capitals of similar size. The general assembly meets there regularly every odd-numbered year. The state capitol, completed in 1840, stands in the middle of a 4 ac. (1.6 ha.) square and is considered a gem of Greek Revival architecture. Capitol square is surrounded by various state buildings (Labor, Library, Agriculture, Revenue, Education, Justice, Highway, and others), all of which have been held to a height not exceeding five or six stories so as not to dwarf the capitol. Various state institutions are in or near Raleigh, including the hospital for the insane (1856), the prison

(1869), and schools for the deaf and blind.

The city has four senior colleges: North Carolina State, formerly State College of Agriculture and Engineering (1887); Shaw University (Baptist, 1865); St. Augustine's College (Protestant Episcopal, 1867); and Meredith College (Baptist, 1891); and two junior colleges for women, St. Mary's (Protestant Episcopal, 1842) and Peace (Presbyterian, 1872). Within a 30-mi. radius are the University of North Carolina, Duke University, North Carolina College at Durham, and the Southeastern Baptist Theological Seminary. To take advantage of this concentration of institutions of higher learning, there has been established near Raleigh the Research triangle, a centre of industrial research. The large number of colleges and universities in the area has resulted in a heavy percentage of college graduates and a high level of cultural interest and activity. The North Carolina Museum of Art in Raleigh is one of the finest institutions of the kind in the area.

Raleigh has long been the major retail shopping centre for eastern North Carolina but in the middle part of the 20th century, due largely to rapid transportation, the volume of trade grew enormously. The city also developed as a wholesale distributing centre, especially for chain food stores.

Industrial volume was small up to the beginning of World War II, but thereafter the city attracted a considerable number of factories producing a wide variety of products. It also became the home office or regional headquarters of a number of insurance companies. In a short period Raleigh changed from a small, slowgoing southern town to a modern, bustling, rapidly expanding city. Its population in 1960 was 93,931; for comparative population figures see table in NORTH CAROLINA: Population. The population of the standard metropolitan statistical area (Wake County) was 169,082 in 1960.

Raleigh was laid off from a tract of forest soon after the American Revolution (in 1792) when North Carolina, like several other of the original states, moved its capital westward from the seaboard. It was named for Sir Walter Raleigh and was incorporated in 1793. During the Civil War Gen. William T. Sherman's army entered the city without opposition in April 1865, and occupied it for the remainder of the war. During the late 19th and early 20th centuries Raleigh shared in the industrial development of the state but its major growth did not take place until during and after World War II. The city has a council-manager form of government, in effect since 1947. Pres. Andrew Johnson was born in Raleigh. (C. Cr.)

RALPH (d. 1122), Norman monk, archbishop of Canterbury from 1114 to 1122, called Ralph d'Escures from his father's estates of Escures, near Sées in Normandy, entered St. Martin's Abbey at Sées in 1079 and became abbot in 1089. Disturbed conditions in Normandy drove him to England in 1103, and he became bishop of Rochester in 1108. As diocesan ordinary of Canterbury, he administered that see after St. Anselm's death in 1109 and was himself elected archbishop in April 1114. His pontificate was chiefly marked by his cooperation with Henry I in the face of papal claims, and by his prolonged but unsuccessful struggle to exact a profession of obedience from Thurstan, archbishop elect of York.

Ralph was a pupil of St. Anselm and should probably be identified with the monk Rodolfus whose works are extant in the Bodleian Library Manuscript Laud Miscellaneous 363 (1). His writings concern some of the theological and philosophical problems expounded by Anselm, to whom his *Meditations* were long attributed. He died on Oct. 20, 1122, and was buried in Canterbury Cathedral.

See N. F. Cantor, *Church, Kingship, and Lay Investiture in England, 1089-1135* (1958); R. W. Southern, "St. Anselm and His English Pupils," *Medieval and Renaissance Studies*, ed. by R. W. Hunt and R. Klibansky, vol. i (1943).

RAMA. Although there are three Ramas mentioned in ancient Indian traditions, the name is specifically applied to the Hindu deity worshiped as the seventh incarnation (*avatar*) of the great god Vishnu. It may be that this Rama was historically a tribal hero of ancient India who because of his virtues and great exploits was later deified. In any case, he is the central figure

of the great epic, the Ramayana (see RAMAYANA, and, for a detailed account of the story of the Sanskrit epic, SANSKRIT LITERATURE). This tale inspired a large popular literature in which Rama and his wife Sita were extolled as personifications of the ideals of chivalry and fidelity. It was also the foundation of the later worship of Rama.

Although Rama was known as an incarnation of Vishnu in the early centuries A.D., there probably was no special worship of him before the 11th century, and it was not until the 14th and 15th centuries that there appeared distinct sects worshipping him as the one, supreme God. Competing with the already established cult of Krishna (*q.v.*), the other great incarnation of Vishnu, the Ramaite sects spread their religion throughout India, and in time Rama's name became the one most often invoked at death as well as one of the most popular in naming children and a form of greeting between friends ("Ram! Ram!").

RAMADAN (the "Scorcher"), the ninth month of the Muslim year. Already sacred to the pre-Islamic Arabs, it became in Islam the holy month of fasting, selected because it was in this month that "the Koran was sent down as a guidance for the people" (Koran ii, 181). Tradition has it that the *lailat al-qadr*, the "Night of Power" (or "of the Decree"), in which the first revelation occurred is to be identified with the 27th of Ramadan. During this night the angels and spirits descend to earth and "it is peace until the rising of the dawn" (xcvii, 3, 5). Ramadan parallels Yom Kippur in its religious function; it, too, constitutes a period of atonement. But whereas the Jewish festival imposes a strict fast of 24 consecutive hours, the Muslim ordinance prescribes abstention from food, drink, sexual intercourse (indeed, any avoidable change of the body's composition) from the moment when "so much of the dawn appears that a white thread may be distinguished from a black" until with nightfall the two become indistinguishable once more (ii, 183), this abstention to be continued throughout the 29 days of Ramadan. Only the very young and the very old, the sick, pregnant and nursing women, and persons on an extended journey may be excused.

Beginning and end of Ramadan are announced when one trustworthy witness testifies before the authorities that the new moon has been sighted; a cloudy sky therefore may delay or prolong the fast. The five daily prayers continue in Ramadan but the addition of the supererogatory prayers, or *tarawih*, at night is considered meritorious, particularly during the last ten days, which are regarded as especially sacred.

In the Koran the development of the Ramadan fast (one of the five "pillars" or absolute requirements of Islam) may be followed from the injunction to fast on Ashura, the Day of Atonement of the Jews (later identified with the tenth of Muharram, the first month of the Muslim calendar), to the command to fast "a certain number of days" during Ramadan (ii, 180) and finally to the month-long fast. The last may have been structured on the Christian Quadragesima (Lent) or comparable Manichaean practices. Fasting has come to be regarded as a most important religious act, and it is observed by many who will neglect their daily prayers. Psychologically a part of it is the Lesser festival or the Festival of Breaking Fast on the first three days of Shawwal when the strain of Ramadan is released (see BAIRAM).

See G. E. von Grunebaum, *Muhammadan Festivals* (1951). (G. E. V. G.)

RAMADI (AR RAMADI), a town and administrative centre of Ramadi liwa' (province) of Iraq, lies on both banks of the Euphrates, 8 mi. (13 km.) N of Lake Habbaniyah, between the Habbaniyah escape channel and the 'Aziziyah Canal, and about 60 mi. (97 km.) W of Baghdad. Though there were earlier settlements (ancient and Abbasid) in the neighbourhood, Ramadi is

modern and was founded by Midhat Pasha in 1869 to encourage sedentarization of the Dulaym tribes. Its importance grew considerably with the establishment of the trans-desert route via Rutbah to the Mediterranean which uses Ramadi as its departure point from the Euphrates. There is also an airfield. A number of former nomads have settled in the town as farmers, and the Dulaym notables have houses there. Though by no means the largest of the upper Euphrates towns, Ramadi is likely to develop further with the extension of irrigation projects in the district.

RAMADI LIWA' (formerly Dulaym [Dulaim]) lies due west of Baghdad from the divide between the Euphrates and Tigris rivers as far west as the frontiers with Syria and Jordan. Area 53,270 sq.mi. (137,969 sq.km.). Pop. (1962 est.) 274,575. Physically, it consists of a portion of the Euphrates Valley and a westward bordering stretch of rolling country that gradually rises westward to the desert plateaus of Syria and Saudi Arabia. The region is the home of the influential Dulaym tribes, some of whom are sedentary farmers living close to the Euphrates banks and cultivating barley and wheat with some rice and fruit. Other Dulaym tribesmen (regarded as organized in ten sections) are pastoral nomads and move extensively between Al Fallujah and Al Qa'im on the Euphrates and regions to the west. (W. B. Fr.)

RAMA (RAMA CHAKRI) DYNASTY, the kings who have been on the throne of Thailand since 1782, when Chao Phaya (Prince) Chakri (or Chakkri) proclaimed himself king at Bangkok.

The previous Thai capital, Ayutthaya, was destroyed and the last of the Ayutthaya kings was put to death by Burmese invaders in 1767. During the following 15 years, General Takh Sin (Taksin), of mixed Thai and Chinese origins, made himself king, restored order, defeated rival Thai kings in the north, held the Cambodians in check, and drove out the Burmese. When Takh Sin went mad in 1782, he was murdered on order of his distinguished general Chakri, who assumed the throne. His descendants have reigned in unbroken line since that date.

RAMA I (1737-1809) defeated his perennial enemies the Burmese and extended his power over Cambodia, Laos, and northern Malaya. He made his kingdom stronger, planned and built the new capital at Bangkok, and gave his people a good administration. He was also effective in reviving Thai culture and was the author of the *Ramakien* and of the first version of the dance-drama *Inao* (see *THAI LITERATURE*). He died on Sept. 7, 1809.

RAMA II (1768-1824) consolidated and improved the reforms introduced by his father and is regarded as the greatest writer of the dance-drama in Thai literature. He was born on Feb. 26, 1768, at Ampawa, where his father had an official position, and was educated at a monastery at Dhonburi. In 1806 he was named heir to the throne, and he succeeded his father in 1809. Rama II is better remembered as a poet, musician, architect, and sculptor than as a ruler, although his reign was notable for renewal of relations with the West and for his legislative reforms. Deeply religious, he was responsible for reviving rituals and for improvements in the classical dance. His greatest achievement was the "second-reign version" of the *Inao*, a poetic dance-drama blending romance and humour, which, despite its legendary Javanese setting, provides interesting details of contemporary life in Thailand. He also composed five other dance-dramas in a less classical style. The king was a skilled musician, and he designed the main temple of Wat Arun and himself carved the doors of the Sakya Temple at Wat Suthat. He died on July 21, 1824.

RAMA III (1788-1851) was the third child and eldest surviving son of Rama II, by his third minor wife. He succeeded his father on the latter's death. During his reign Thailand entered into unequal treaties with Great Britain and the United States, which expanded trade on terms favourable to the Western powers. Disputes with Great Britain led to the reduction of Thai power over its vassal states in northern Malaya. He died on April 2, 1851.

RAMA IV (reigned 1851-68), King Mongkut, exerted vigorous efforts to modernize his kingdom; he employed foreign advisers and invited the Chinese to enter Thailand to work and to trade. He signed treaties, first with England and then with other nations, which gave foreigners the right to reside in Thailand, to

engage in limited trade with tariff concessions, and to enjoy the privileges of extraterritoriality. (See further *MONGKUT*.)

RAMA V (reigned 1868-1910), King Chulalongkorn, was benevolent and just and devoted to internal reform, which he capped with the abolition of slavery. He modernized the army and the civil service and introduced such Western innovations as electricity, telegraphy, streetcars, and railways. In spite of his sagacity he lost territory to the British in Malaya and Burma and to the French in Indochina. He preserved his independence by taking advantage of the mutual jealousies of British and French and the refusal of either to let Bangkok pass under the control of the other. (See further *CHULALONGKORN*.)

RAMA VI (1881-1925), Prince Vajiravudh, son of Chulalongkorn, is remembered as a liberal, progressive ruler and as a prolific writer. He was born on Jan. 1, 1881, at Bangkok, and educated there and in England, at Oxford and Sandhurst. He succeeded his father in 1910. Although he has come to be regarded in Thailand as a notable ruler, his reign was unpopular. His refusal to grant a democratic constitution, for which he thought his people unready, disappointed liberal elements; his progressive policies annoyed the conservatives; and the fact that he was unmarried and lived in seclusion turned popular feeling against him. His devotion to English traditions led to such unwise actions as the formation of the "Wild Tiger" volunteer force, paid from his private income, to supplement the regular army; and the liberal idealism which caused him to sacrifice revenue by closing the gambling houses (1917) and discouraging opium smoking was not welcome either to the financiers or to the people. More successful was his law of 1916, making use of surnames compulsory. Interested in education, he founded Chulalongkorn University in Bangkok and was responsible for legislation making education free and compulsory. He welcomed the opportunity to enter World War I, at the invitation of the United States in 1917, and was largely instrumental at the peace conference in negotiating the treaties (signed by his successor) by which the Allies surrendered their extraterritorial and fiscal rights in Thailand.

Rama VI introduced Western forms into Thai literature, in particular the dialogue drama. Author of about 50 original plays, he also adapted more than 100 by English and French dramatists; and his translations of three of Shakespeare's plays introduced blank verse to Thailand. He was also a pioneer of the novel and a poet. Rama VI died at Bangkok on Nov. 26, 1925.

RAMA VII (1893-1941), King Prajadhipok, brother of Rama VI and the 76th child and youngest son of Chulalongkorn, was born on Nov. 8, 1893, and succeeded to the throne on his brother's death. He lost the prerogatives of an absolute monarch after the revolution of 1932 and abdicated in March 1935. He died in England on May 31, 1941.

RAMA VIII (1925-1946), King Ananda Mahidol, nephew of Rama VII, was born on Sept. 20, 1925. As king, he saw his country suffer on the losing side of World War II, and he lost his life during the night of June 8-9, 1946, under mysterious circumstances, before he was able to see the return of prosperity.

RAMA IX (1927-), King Bhumibol Adulyadej, brother of Rama VIII, was born on Dec. 5, 1927, at Cambridge, Mass., where his father was studying at Harvard. Although as king he exercises no real political power, he is the symbol of the state and he enjoys the universal respect of his people. Carrying on his family's traditional interest in the arts, he is a jazz clarinet player and composer. See also *THAILAND: History*.

See Prince Chula, *Lords of Life: the Paternal Monarchy of Thailand, 1782-1932* (1960); W. F. Vella, *Siam Under Rama III* (1957).

(C. A. B.; D. N. K. B. P.)

RAMAKRISHNA (1836-1886) is perhaps the best-known Hindu saint of modern times. In a world giddy with material power and achievements, callous to human suffering and misery and indifferent to the higher life of the spirit, he presented an ideal of holiness and compassion. He was born in the village of Kamarpukur in Hooghly district, Bengal, on Feb. 20, 1836, to an orthodox Brahman father and a mother of character and piety. From his youth, he was attracted by the lives of religious heroes and he had his first experience of spiritual ecstasy at age seven.

When he was 23 he was married to a girl of five, Saradamani Devi. The marriage, even after his wife had grown up and went to live with him, did not weaken in any way his fervent devotion to God. To him Kali was the Divine Mother. Ramakrishna took to the worship of Rama and felt that Rama was the spirit of the universe. He later adopted the worship of Krishna and practised the Vaishnava form of love, in which the human soul loves God as a devoted wife loves her husband. Toward the end of 1866, he practised the discipline of Islam under the guidance of a Muslim teacher, and in 1874 he adopted the methods of Christianity. Thus, he had visions of Rama, Krishna, Shiva, Kali, Allah, and Jesus. He said, "I have found that it is the same God toward whom all are directing their steps, though along different paths."

BY COURTESY OF INFORMATION SERVICE OF INDIA, LONDON
RAMAKRISHNA. PHOTOGRAPHED ABOUT 1881

Ramakrishna spent the last years of his life in the spiritual education of his fellowmen. He died of cancer on Aug. 16, 1886. His famous disciple Vivekananda said of him, "It was no new truths that Ramakrishna came to preach, though his advent brought old truths to light."

RAMALHO ORTIGÃO, JOSÉ DUARTE: see ORTIGÃO, JOSÉ DUARTE RAMALHO.

RAM ALLAH, a town in the Hashemite Kingdom of Jordan, about 10 mi. (16 km.) N of Jerusalem on the road to Nablus (Nabulus), at an altitude of nearly 3,000 ft. (914 m.). The population (14,759 in 1961) is largely Christian. Its elevation makes it a popular summer resort, and it has several modern hotels. The broadcasting station for Jerusalem is also at Ram Allah. A large camp of Arab refugees from Palestine is situated immediately south of the town. The scanty remains of early occupation of the site date from Byzantine and medieval times. (G. W. L. H.)

RAMAN, SIR CHANDRASEKHARA VENKATA (1888–), Indian physicist, received the Nobel Prize for Physics in 1930 for his work on the diffusion of light. Raman discovered that the light scattered by any medium contains frequencies differing from that of the incident light by amounts which are characteristic of the scattering medium. These characteristic Raman frequencies are equal to the infrared frequencies of the substance and are caused by energy interchanges between the incident light and the scattering substance. However, some frequencies appear in the Raman spectrum which are "forbidden" in the infrared, and vice versa, so that studies of infrared and Raman spectra complement as well as confirm one another.

Less well known than the Raman effect (*q.v.*), but perhaps more important, was Raman's influence in stimulating interest in, and securing support for, scientific research in India. He contributed to the building up of nearly every research organization in India; he founded the *Indian Journal of Physics* and the Indian Academy of Sciences; he trained hundreds of students and sent them to important posts in universities, colleges, and government work throughout India and Burma.

Raman was born at Trichinopoly (Tiruchirapalli), Nov. 7, 1888. He graduated from Presidency College in Madras and received a master's degree in 1907. He had already completed researches in optics and acoustics; but since there was at that time no opportunity for a scientific career in India, he entered the finance department of the Indian government, securing his position by

competitive examination at the age of 19.

Continuing his researches in his spare time, he finally came to the attention of the authorities of the University of Calcutta, who offered him a professorship of physics in 1917. Raman was knighted in 1929. In 1933 he moved to the Indian Institute of Science at Bangalore as head of the department of physics. In 1947 Raman was named director of the Raman Research Institute at Bangalore. In 1961 he became a member of the Pontifical Academy of Sciences.

See N. H. de V. Heathcote, *Nobel Prize Winners in Physics* (1953). (P. O.)

RAMANATHAPURAM (formerly RAMNAD), a town and district in the south of Madras, India. The town lies at the base of the peninsula that faces the island of Rameswaram (*q.v.*) in Palk Strait, 63 mi. (101 km.) SE of Madurai. Pop. (1961) 26,890.

RAMANATHAPURAM DISTRICT (area 4,849 sq.mi. (12,559 sq.km.); pop. [1961] 2,421,788) is one of the driest and most infertile tracts in Madras, almost dead level and sandy. The district headquarters is at Tallakulam at Madurai. The titular head is the raja of Ramnad, the chief of the local Maravar (Maravan) community. His title is *Setupati* or "lord of the causeway" (the ridge of rock connecting the island of Rameswaram with the mainland). At Karaikudi to the north, mainly through the munificence of Alagappa Chettiar and subsequently with governmental aid, a large educational centre has sprung up with colleges of arts and science, engineering technology, and teachers' training, all affiliated to Madras University. (G. KN.)

RAMAN EFFECT, a change in wavelength of light that is scattered by molecules. When a beam of monochromatic light traverses a pure, dust-free, transparent sample of a chemical compound, a small fraction of the light is scattered in directions other than the direction of the incident beam. Most of this scattered light is of unchanged frequency or wavelength. A small part, however, has frequencies different from that of the incident light; its presence constitutes the Raman effect.

The name honours Indian physicist Sir Chandrasekhara Venkata Raman (*q.v.*), who reported (*Indian Journal of Physics*, vol. 2 [1928]) that he observed the effect after extended researches on light scattering. The possibility of such an effect had been predicted theoretically by A. Smekal in 1923. Soviet physicists G. S. Landsberg and L. I. Mandelstam observed the phenomenon independently (in quartz) at about the time of Raman's announcement; Raman's paper, however, represented a much more thorough study.

Raman scattering is perhaps most easily understandable if the incident monochromatic light is considered as consisting of photons (with energy proportional to frequency) that can collide with the molecules of the sample. Most of the collisions are elastic and the photons are scattered with unchanged energy and frequency. Some collisions, however, are inelastic; *i.e.*, the molecule takes up energy from or gives up energy to the photon, which is thereby scattered with diminished or enhanced energy, hence with lower or higher frequency. The frequency shifts are thus measures of the amounts of energy involved in the quantum transitions of the scattering molecule.

The Raman effect is very feeble; for liquids its intensity may be only about 10^{-6} of that of the incident beam. With large samples and very intense irradiation the effect becomes visible; but it is usually photographed with a luminous spectrograph. A convenient alternative employs a sensitive photomultiplier cell, the suitably amplified electric signal being used to give a written record of the spectrum. Visible light is most frequently used to excite the effect, especially the intense blue line of the mercury arc spectrum. Every incident line produces its own Raman lines, but confusion may be avoided by using filters.

The pattern of Raman lines is characteristic of the particular molecule species, and its intensity is proportional to the number of scattering molecules present. Thus Raman spectra are used in qualitative and quantitative chemical analysis; this in no way impairs or consumes the sample and may be used for the study of such labile equilibria as the ionic dissociation of electrolytes in solution. Commercially available Raman-effect recording instru-

ments are used, for example, in the petroleum industry.

The energies corresponding to the Raman-frequency shifts are found to be the energies of rotational and vibrational quantum transitions of the scattering molecule. Pure rotational shifts are small and difficult to observe, except for those of simple gaseous molecules. In liquids rotational motions are hindered and discrete rotational Raman lines are not found. Most Raman work is concerned with vibrational transitions, which give larger shifts observable for gases, liquids, and solids. Gases have low molecular concentration at ordinary pressures; thus liquids and solids are more frequently studied. A vibrational Raman line shifted to lower frequency (Stokes line) is more intense than the corresponding line shifted to higher frequency (anti-Stokes line); for the former involves an upward transition from the ground vibrational state, while the latter reflects a transition from an excited vibrational state—and the ground state has a larger population of molecules than the excited state.

According to quantum theory only those molecular rotations and vibrations are permitted in which the motion (considered classically) is associated with a change in the electric polarizability of the molecule (see MOLECULAR SPECTRA). This is because the Raman effect may be regarded as arising from the oscillating dipole induced in the molecule by the electric field of the incident radiation. This condition for the appearance of a Raman line is essentially different from that which permits rotational or vibrational absorption. Thus, although infrared absorption spectra can also give vibrational frequencies of molecules, the two methods are essentially complementary; for frequencies that are forbidden in absorption may be permitted in the Raman effect and vice versa.

The theory shows that the number of fundamental vibrational frequencies permitted in the Raman effect depends on the number of atoms in the given molecule, and on the symmetry of their arrangement. This permits empirical discrimination among proposed possible structures for a given molecule; for example, a molecule XY_2 (where X is the central atom) has only one permitted vibrational Raman line if the structure is linear, but three if it is bent.

Another important observable property is the state of polarization of the Raman lines for scattering at right angles to the incident light. The theory shows that spectral lines should differ in degree of polarization depending on the symmetry of the scattering species. Observations of polarization thus provide further evidence on molecular structure.

After 1952 the so-called Resonance Raman effect, foreseen as early as 1934, was investigated experimentally (notably in the U.S.S.R.). This is seen as an enhancement of the intensity of Raman scattering when the frequency of the incident radiation approaches an electronic absorption band of the scattering substance. Of considerable theoretical interest, the resonance effect may have practical value for identifying molecules at low concentrations.

In addition to their uses for analysis and determination of molecular symmetry, Raman spectra yield molecular moments of inertia and vibrational frequencies. Isotopic substitution (especially by deuterium) increases the obtainable information, which may be used for such calculations as those of thermodynamic quantities and intramolecular force fields. (L. A. Wo.)

RAMANUJA (d. A.D. 1137), one of the greatest Indian thinkers and religious leaders, was a Tamil Brahman born, according to tradition, in 1017 at Sriperumbudur near modern Madras. He was a member of the Shrivaiśnavas (see VISHNUISM), ardent worshipers of Vishnu, becoming their devoted head at the temple of Shri-rangam near Tiruchirapalli (Trichinopoly), where, after years of teaching, travel, and exile, he died. Ramanuja gave philosophic expression to the Shrivaiśnava doctrine

of *vishishtadvaita*, "the nonduality [i.e., ultimate oneness] of the differentiated," uniting the implicit conceptions of the Alvars' impassioned Tamil hymns with the metaphysics of the Upanishads. The nine Sanskrit works attributed to him include: *Vedartha-samgraha*, deriving this doctrine from the Upanishads; *Shri-bhashya*, an extensive commentary on the Vedānta Sūtras; *Vedānta-dīpa* and *Vedānta-sara*, summarizing his *Shri-bhashya*; and *Gita-bhashya*, a commentary on the Bhagavad Gita, emphasizing *bhakti*. Brahman, to Ramanuja, is above all a personal godhead: as Vishnu-Narayana one with whom souls, by nature akin to God, commune. Divine grace, initiating and perfecting the souls' eternal freedom and bliss, not infusing but releasing their divine life, removes the blindness and fetters wrought in beginningless time by ignorance and *karma* (q.v.), and stirs from the soul's depth a spiritual response as *bhakti*; and *bhakti*, to Ramanuja, is less religious emotion than intuitive and loving knowledge of God. See also INDIAN PHILOSOPHY: *Six Systems: Vedānta*; HINDUISM: *Philosophical and Theological Schools*.

(O. A. La.)

RAMANUJAN, SRINIVASA (1887–1920), Indian mathematician who contributed to the theory of numbers, was born at Erode, southern India, on Dec. 22, 1887. His full name was Srinivasa Ramanuja Ayengar. He was educated at the town high school and at the Government College at Kumbakonam. He obtained a scholarship from the University of Madras, but after his marriage, in 1909, became a clerk in the Madras Port trust. Correspondence with G. H. Hardy of Cambridge led to his obtaining a further scholarship from Madras University, and a grant from Trinity College, Cambridge. In spite of religious difficulties arising from the fact that he was a Brahman, he came to England in April 1914, where Hardy, by private teaching, helped to provide the necessary mathematical background for his original work. His mathematical work is on the theory of numbers, theory of partitions, and the theory of continued fractions. He became ill in 1917, returned to India in 1919, when he resumed some of his mathematical work, but died on April 26, 1920, at Kumbakonam. He was elected a fellow of the Royal Society in 1918 and a fellow of Trinity College later in the same year.

Ramanujan's notebooks were published in 1957; his *Collected Papers* were published in 1927 and 1962.

See G. H. Hardy, *Ramanujan* (1940); J. R. Newman, "Srinivasa Ramanujan," in *Lives in Science* (1957).

(O. Or.)

RAMAT GAN (meaning "garden hill"), a town of Israel in the plain of Sharon, lies 2 mi. E of Tel Aviv-Jaffa, with which it is linked by continuous habitation and by a frequent bus service. Pop. (1961) 90,234. It was founded in 1921 and, unlike Tel Aviv-Jaffa, is built on hills. Ramat Gan contains residences of diplomatic missions, many public gardens, the main football (soccer) and athletics stadium of Israel (where the Israel Maccabiah, the athletic championship, is held), a technical school and the religious University of Bar Ilan (founded in 1954). There are light industries including citrus by-products and the manufacture of chocolate and building materials. (No. B.)

RAMA TIBODI I (1312–1369), warrior-king and lawgiver of Thailand, proclaimed himself king at Ayutthaya in 1350 and thereby founded a dynasty that lasted until 1767. As a warrior, he overcame his neighbors, including the decadent king of once-powerful Sukhothai, and fought continuously and successfully against the Khmers in Cambodia to the east and the various peoples of Burma to the west. He pushed his domains southward toward Malacca in the Malay Peninsula, and was careful not to antagonize the strong new Ming emperors in China.

As lawgiver, Rama Tibodi codified laws which had existed since the Nanchao period (7th to 13th centuries A.D.); these laws were generally observed until the latter days of the 19th century. Among them were the Laws of Evidence, which barred many types of persons from giving evidence; the Law on Offenses Against the Government, which fixed severe penalties for violations against the state; the Law on Abduction, which aimed to prevent kidnapp-

ping and the stealing of slaves; and the Law of Husband and Wife, which recognized polygamy and provided for easy divorce by mutual consent. (C. A. B.)

RAMAYANA ("Life of Rama") is the shorter of the two great national epic poems of India, the longer being the *Mahabharata* (q.v.), and consists of about 24,000 couplets. Composed in Sanskrit, c. 300 B.C.; by Valmiki, and divided, with various later additions, into seven books, it describes the royal birth of Rama in the kingdom of Ayodhya (Oudh), his tutelage under the sage Vishvamitra, culminating in his success in bending King Janaka of Videha's mighty bow and thus gaining the king's daughter Sita in marriage. Banished from his position as heir-apparent by an intrigue, he retreats with his wife and favourite brother, Lakshmana, to the forest, where the demon king Ravana seizes Sita and carries her off to his kingdom in Lanka (Ceylon). The rest of the epic describes Rama's struggle to rescue her, aided by his brother and by a vast army of monkeys and bears, and it ends with Ravana's defeat and Rama's return to claim his throne. Always popular throughout India, the story has spread in various forms throughout Southeast Asia.

RAMAZZINI, BERNARDINO (1633–1714), Italian teacher of medicine, who is considered to have been the founder of the study of occupational diseases and of workmen's protection, was born at Carpi near Modena, Italy, on Nov. 3, 1633. He took his medical degree at the University of Parma in 1659 and was appointed in 1671 the first professor of medicine at the University of Modena. There he made accurate studies in epidemiology, describing outbreaks of lathyrism (chickpea poisoning) and malaria. But his lifework began when one day he witnessed the distress of a workman cleaning out the cesspit in his own house. Subsequently Ramazzini investigated many crafts which were the cause of grave injury to those who practised them, and made a striking addition to the Hippocratic teaching: "When a doctor visits a working-class home he should . . . ask also 'What is your occupation?'" In 1700 he accepted the chair of medicine at Padua University, offered to him by the Venetian senate, and his fame spread rapidly all over Europe. In spite of lifelong ill health, he devoted much time to the study of harmful occupations, whether dirty or dangerous. His work *De Morbis Artificum Diatriba* (1713) exhorted doctors to demand laws for the protection of the health of workers. Ramazzini died in Padua on Nov. 5, 1714. (Do. H.)

RAMBOUILLET, CATHERINE DE VIVONNE, MARQUISE DE (1588–1665), French society hostess, was born in Rome in 1588, into the aristocratic Savelli family (of which in her signature she kept the name) which traced its descent from the Strozzi and Medici families. She was brought up to speak Italian, later learned Spanish, and by the turn of the century was established with her husband in Paris. She acquired by legacy a house in the Rue Saint-Thomas du Louvre (a street later demolished to make way for extended palace gardens) and this house, rebuilt to her own design, became known as the Hôtel de Rambouillet. As a meeting place of the best Parisian society, from 1620 until the Fronde and even in a small way after 1650, it remained open till the death of its mistress on Dec. 2, 1665.

She was a woman of ideas and imagination and achieved the initial novelty of providing a house and garden to which intelligent and fashionable people were attracted. She planted sycamores for seclusion and flower beds in ingenious patterns; she built rooms with large windows, new pictures and plenty of chairs, culminating in the famous blue reception room. Into this refreshingly new milieu she attracted much of the high society of Paris, and most of the writers who are still remembered.

How this heterogeneous assembly was held together for so many years is a puzzle, but the personality of Catherine de Vivonne seems to have been the dominating influence. Outwardly she was, it seems, persuasive rather than domineering. It was not difficult to please her, writes Tallemant des Réaux, for she never asked

anything unreasonable. Recent research suggests that she did not make of the Hôtel primarily a literary salon at all, but rather a social meeting place of elegant people. She thus taught her contemporaries the art of conversation, an art which a generation only once removed from civil war, and accustomed to the masculine swashbuckling of the court of Henry IV, had to learn afresh. The Hôtel thus became a nursery of gentility, of civility, of that politeness which produced the new concept of the *honnête homme* and which was to find its artistic sublimation in Molière's *Le Misanthrope*. Catherine de Vivonne's great achievement was to impose this discipline of manners on a proud social set, on the Condé family in the first place and on their friends Mme du Vigan, Mme de Combalet, and Mme de Sablé. These people, though free in manners and morals, were, it seems, willingly tamed by a hostess about whom through the years no breath of scandal gathered. Discussion seems to have avoided dullness. The marquise was fond of entertainments, excursions, charades, even practical jokes. Perhaps her brightest idea was to commit much of the entertaining to literary men, bourgeois, practised in discussion and expression, such as Malherbe, Jean Chapelain, the abbé d'Aubignac, and, above all, Vincent Voiture. This master of light verse was the life and soul of the gatherings; he inspired successive fashions, of madrigals, of "metamorphoses" (in which a person was described as a flower or an animal), of sonnets. A famous example of this teamwork is the *Guirlande de Julie* (q.v.).

There is no evidence that the Hôtel, as was long thought, was the home or origin of preciosity, though clearly a standard of speech and bearing would tend in lesser hands to become precious. With even greater success it seems to have avoided pedantry. Plays were read, performed, and criticized, but the theorists were not allowed to pontificate and, significantly, figures who tended to lay down the law, such as J. L. Guez de Balzac, Richelieu, Corneille, rarely went to the Hôtel. Richelieu's dominance of the new Académie Française indeed contrasts sharply with the freedom from political control of the Hôtel, where in the later years the Fronde cliques seem to have formed. The Hôtel may be said to have put into practice the polite ideal sketched in the ever-popular novel *L'Astrée* (1607–27), by Honoré d'Urfé, and thus to have been the first of that long line of Paris salons which formed the setting and inspiration of writers as different as La Fontaine, Voltaire, and Proust.

See G. Tallemant des Réaux, *Historiettes*, ed. by A. Adam, 2 vol. (1960); É. Magne, *Voiture et l'Hôtel de Rambouillet*, 2 vol. (1929–30). (W. G. ME.)

RAMBOUILLET, a town of north-central France, headquarters of an *arrondissement* of the Yvelines (formerly of the Seine-et-Oise) *département*, situated in a thickly wooded country formerly known as the forêt des Yvelines but now generally known as the Forest of Rambouillet. It is about 31 mi. (50 km.) SW of Paris and 19 mi. (30 km.) from Versailles. Pop. (1962) 10,631.

Rambouillet's famous château, built on ancient royal land in the 14th century, now dates mainly from the 18th century. The estate has had a succession of famous owners, among whom were the Montfort family (11th century); the d'Angennes family, to which the husband of the celebrated Marquise de Rambouillet belonged; the family d'Uzès; the house of Bourbon-Toulouse; Louis XVI; Napoleon I and the sovereigns who followed him. Francis I died there in 1547; Napoleon I stayed there before his departure for St. Helena; and there Charles X signed his abdication in 1830. Rambouillet became a marquiseate in 1612, and a duchy in 1711. Since the time of Félix Faure (elected president in 1895) it has been the country residence of the presidents of France. In the large park of the château is a zootechnical centre, which replaced the *bergerie nationale* (national sheepfold) and which has maintained the direct strain of the Merino sheep imported from Spain under Louis XVI.

Rambouillet is a hunting centre, and there is shooting in its forest reserved for the president. The region is of historical interest, with notable châteaux as well as picturesque scenery. The attractive upper valley of the Yvette River, known as the Vallée de Chevreuse, is much visited by Parisians.

RAMEAU, JEAN PHILIPPE (1683–1764), the greatest French composer of the 18th century, known also for his theoretical works on harmony, was baptized at Dijon on Sept. 25, 1683. He was thus born two years before J. S. Bach, Handel, and Domenico Scarlatti, all of whom he was to survive. His father was an organist, and at 18 he himself decided to become a musician. In 1701 he went to Italy, but only reached Milan and returned a few months later. He became organist successively at Avignon, Clermont-Ferrand, Paris, Dijon, Lyons, and again at Clermont-Ferrand, which he left in 1722 for Paris, where he settled for the rest of his life. For about 20 years, until 1753, he was in the service of the tax-farmer Le Riche de la Pouplinière, conducting his private orchestra and ministering to his musical needs. Rameau died in Paris on Sept. 12, 1764.

Before the age of 50 Rameau had published harpsichord pieces, a few motets, and some solo cantatas, and had written a little light music for the stage; but it was only later, from his position in La Pouplinière's circle, that he was able to turn fully to opera, in which he produced his masterpieces. In 1733 his *Hippolyte et Aricie* was produced at the Paris Opéra. From then until 1760 he wrote tragic operas, various forms of ballet-opera, pastorals, and comic operas. His tragic operas and pastorals are in the form created by J. B. Lully and Philippe Quinault; his ballet-operas follow the form used by André Campra and A. H. de La Motte; and in *Platée* (1745) he adapted for the first time the form of the *tragédie lyrique* to a comic plot.

None of his librettists, not even Voltaire, was a great dramatist, and Rameau himself was too unheeding of dramatic structure to criticize their plots, though he would dwell on details. Yet when the plot allowed it, he identified himself with his characters, e.g., *Thésée* in *Hippolyte et Aricie* and *Iphise* in *Dardanus*, entering into their feelings with great imagination. He was also able vividly to portray a tragic situation; e.g., Hippolyte's death, and the tragic suspense in the second entry of *Les Fêtes d'Hébé*. His recitative, unlike that of Italian opera composers, is expressive and shades away smoothly into the airs. His harmony is rich and dense and his bass line interesting, its coherence and power often making his harmonies more telling than the vocal line itself. His many choruses are outstanding, the earlier being longer and less dramatic, and the finest being those in the four tragedies, *Hippolyte et Aricie*, *Castor et Pollux* (1737), *Dardanus* (two versions: 1739 and 1744), and *Zoroastre* (1749). The orchestral accompaniment is often of great beauty and interest in itself. Though consisting only of strings, woodwind, horns, and occasionally trumpets, Rameau's orchestra is used with an almost impressionistic resourcefulness. The orchestra is used alone in the *symphonies*, in the form of dances during the interludes, *ballets figurés*, and sections of dumb show. Rameau's dances are the most immediately appealing part of his work. Highly sophisticated, they are nevertheless based on folk models. The finest of his *ballets figurés* are found in works on pastoral subjects, a genre in which Rameau was particularly successful, often displaying bold harmony and picturesque orchestration.

His masterpieces are the comedy *Platée*, his first two ballet-operas *Les Indes Galantes* (1735) and *Les Fêtes d'Hébé* (1739), and his first three tragedies. Of these *Hippolyte et Aricie* is the most consistently tragic and musically daring, though the most unequal; *Castor et Pollux* is the most homogeneous and is elegiac rather than tragic, with delicate shades of feeling; *Dardanus*, in its two very different versions, covers a wide range of emotion and is musically the richest.

Rameau's three books of solo harpsichord pieces and his five trios (*Pièces de Clavecin en concert*) are more advanced than Couperin's in keyboard technique, and show the same harmonic vigour and concentrated expression as his operas. The trios are early examples of chamber music with an independent keyboard part instead of merely a figured bass. His four motets and his solo secular cantatas, all early, are among the less distinctive examples of his work.

Among his theoretical works, the *Traité de l'harmonie* (1722), based on the acoustic discoveries of the mathematician Joseph Sauveur (1653–1716), presents an explanation of harmonic prac-

tice of the time. For Rameau's theory of the "fundamental bass" see HARMONY: *Treatment of Dissonance*.

As a person, Rameau was silent and reserved. His wife, whom he married when he was middle-aged, declared that she knew nothing of the first 40 years of his life. Austere and unbending, he remained remote from the intrigues of the contemporary musical world. He fought in defense of his theoretical views, to which he attached more importance than to his creative achievement; and it was on these theoretical matters that he quarreled with the mathematician D'Alembert, who had earlier been his admirer and supporter. Statements about his miserliness are largely slander, nor should any faith be put in the portrait of him in Diderot's satire *Le Neveu de Rameau* ("Rameau's Nephew"). He was a noble, forbidding figure, hardly at ease in the milieu in which he moved.

See P. M. Masson, *L'Opéra de Rameau* (1932); Cuthbert Girdlestone, *Jean-Philippe Rameau: His Life and Work* (1957).

(C. M. G.)

RAMESWARAM, a town in Ramanathapuram (Ramnad) district of Madras, India, on Rameswaram Island in Palk Strait, 93 mi. (150 km.) SE of Madurai, with which it is linked by a railway bridge. Pop. (1961) 6,801. It contains one of the most venerated Hindu shrines, which in sanctity is second only to Kashi (Benares, now Varanasi). The great temple dates from the 17th century, although according to tradition it was founded by Rama, the hero of the epic *Ramayana* (q.v.), to commemorate his successful expedition to Ceylon across Adam's bridge (q.v.). It is quadrangular in shape, about 1,000 ft. (305 m.) long and 650 ft. (198 m.) broad, with a 100-ft. (30 m.)-high gopura (tower gate) and 700-ft. (213 m.)-long side corridors which open into richly decorated transverse galleries. It is perhaps the finest example of Dravidian architecture. Critics, however, consider its design a mixture of the exquisite and the inferior.

(G. KN.)

RAMIE. Ramie is a textile fibre of the soft or bast fibre group, which occur as longitudinal strands in the inner bark of dicotyledonous (broadleaf) plants. The individual cells of the fibre bundles are botanically true fibres—elongated and thick walled with characteristic pitting. These cells are tenaciously gummed one to the other to form the cablelike strands which become commercial fibre when once freed from other bark tissues. The ramie or "China grass" plant is a many-stemmed shrub, *Boehmeria nivea*, of the nettle family (Urticaceae). The variety *tenacissima* is called Rhea. Slender stems as much as eight feet long bear heart-shaped leaves with a whitish underside along the upper third of the stalk. At their base the stems may be nearly an inch thick and contain there the most abundant fibre. The ramie plant is perennial, new stems arising from the crown after

WALTER SINGER

RAMIE (BOEHMERIA NIVEA) LEAVES

the old are cut. A planting should endure for several years, with about three harvests annually. The species prefers warm humid climate and rich soils and should be fertilized generously to maintain good stands.

Ramie has been under cultivation from time immemorial. It was grown in ancient Egypt, where it was used to wrap mummies. Presumably it is native to China and Formosa and is mentioned in Chinese literature as early as 2200 B.C. Since 1855 it has been planted sporadically in the southern United States. Several attempts at European culture have been unsuccessful.

Fibres.—The fibres themselves are strong (eight times more so than cotton), durable and of fine texture and good colour. The cells are among the longest of natural fibres—up to one foot long but only $\frac{7}{80}$ in. in diameter. Ramie is superior in many respects to flax, hemp and jute. Its chief liability, however, has been the difficulty of freeing the fibre bundles from the gummy ensheathing tissues and inability to adapt the crop to large-scale mechanized handling. Production lagged behind major fibres, running only about 20,000 or 25,000 tons annually, produced mostly in China, with exports largely to Japan and Europe. In the United States it has continued as a minor crop in Florida, Louisiana, Texas and California.

Retting.—Retting is the process of freeing stem fibres by bacterial decomposition (rotting). The thin-walled cells of softer tissue decompose more readily than thick-walled resistant fibres. Immersing the stems or exposing moistened stems to air usually fails to decompose the cementing gums of ramie, so that the fibre must be separated by pounding and scraping and even then contains up to one-fourth its weight as resin. Eventually the resin or gum must be dissolved chemically. The fibres then become flexible and smooth—so smooth, in fact, that spinning becomes difficult on machinery developed for other fibres. In the far east harvest is by hand a stalk at a time. Each stem can be selected for proper maturity. The limited production in the U.S. is harvested by machine. Much ramie is homespun in the east, with little final cleaning. This gives a coarse, although enduring, fabric. Adhesive gums can be removed by procedures such as boiling in lye, or sometimes an acid treatment, bleaching or induced retting. Degummed fibre is washed, then "softened" with glycerin, waxes or soaps. Spinning is usually on machinery designed for silk or other fibre. Most ramie fabric includes a percentage of some other fibre, such as wool or cotton. It has been used in fire hose, fishing nets, propeller-shaft packing, hats, upholstery and various fabrics. Clothing made of ramie cloth wears well and is said to be mothproof.

(R. W. Sy.)

RAMIRO, the name of two kings of Aragon.

RAMIRO I (d. 1063), bastard son of Sancho III (d. 1035) of Navarre, was the first king (1035–63) of Aragon. During his father's lifetime he ruled this territory as *regulus* from 1011 and was nominated king of it in his father's will. On the death (1045) of his brother, Gonzalo, he annexed the latter's kingdom of Sobrarbe and Ribagorza and later added the county of Pallars to his dominions. Ramiro conquered a large number of valleys in Upper Aragon from the Moors and made the Moorish kings of Huesca, Saragossa, and Lérida his tributaries. With them he attacked, unsuccessfully (1043), his half brother García, king of Pamplona. He was killed at Graus (May 8, 1063) when campaigning against the king of Saragossa and Sancho of Castile.

RAMIRO II (d. 1157), called "the Monk," king of Aragon from 1134 to 1137, third son of Sancho V Ramírez, was a monk and bishop-elect of Barbastro when he was elected to the Aragonese throne on the death (1134) of his brother, Alfonso I. Navarre under García V Ramírez thereupon successfully reasserted its independence from the Aragonese crown. Ramiro soon quarreled with the Aragonese nobles and was temporarily expelled from his kingdom by them. He crushed this revolt (late 1135) with the aid of Ramón Berenguer IV, count of Barcelona. Early in 1136 Ramiro married Agnes of Aquitaine and had by her a daughter, Petronilla. He at once caused this infant to be betrothed to his ally Ramón Berenguer and himself abdicated in her favour (August 1137), leaving the government of Aragon in the hands of Ramón Berenguer. The latter's marriage to Petronilla duly took

place in 1150. Ramón Berenguer died in 1162 and, in 1164, Petronilla formally renounced the Aragonese crown to her son, Alfonso II. The crowns of Aragon and Catalonia were thus united under the house of Barcelona by Ramiro's renunciation after the Aragonese kingdom had existed for only 100 years. Ramiro himself lived in retirement at the priory of San Pedro el Viejo at Huesca until his death on Aug. 16, 1157. (P. E. R.)

RAMKHAENG (RAMA KHAMHENG) (reigned 1275–1317), warrior and conqueror, fourth king of Sukhothai in Thailand, earned the title Rama the Great because he converted a young and struggling state into a powerful kingdom. He maintained friendly relations with his neighbours in Thailand, but fought against formidable enemies in Cambodia to the east and Burma to the west and extended his sway southward over part of the Malay Peninsula. He enjoyed the favour of the emperor Kublai Khan in China and twice made personal pilgrimages to Peking.

Ramkhaeng also achieved greatness for his accomplishments in times of peace. He made his kingdom the cradle of Thai civilization, borrowing freely from the cultural riches of his neighbours; adopting their political ideas, their social systems, and their Buddhist religion with its beliefs, ceremonies, temples, and ornaments of artistic beauty. The invention of the Thai alphabet occurred during his reign and is generally attributed to him. An inscription at Sukhothai, describing Ramkhaeng's justice, magnanimity, and religious devotion, is the earliest extant specimen of the Thai language. (C. A. B.)

RAMLE (RAMLEH; Hebrew RAMLA), a town of Israel in the plain of Sharon contiguous with Lod (Lydda), lies 12 mi. (19 km.) SE of Tel Aviv-Jaffa. The population, (1961) 22,444, is composed mostly of Jewish immigrants from Asia and North Africa including heretical Karaites from Egypt and the U.S.S.R. The town was founded A.D. 716 by the Arab conqueror Sultan Suleiman to replace Lod (q.v.) as the administrative centre of Palestine. Its name was derived from the Arabic 'raml' meaning "sand." Of the famous White Mosque erected by him, only the tower remains. The crusaders made it one of their principal strongholds and called it Rama. The Muslims reconquered and razed the town, but it was rebuilt in the 14th century. Napoleon made Ramle his headquarters in 1799. It was several times wholly or partly destroyed by earthquakes, the last one being in 1927. The British War Cemetery there is one of the largest in the Middle East. A cement factory has been established and the town is linked by rail and road with Tel Aviv-Jaffa, Jerusalem, and Haifa. (No. B.)

RAMMED EARTH (PISÉ DE TERRE) is a building material resulting from the application of compaction to certain soils. Of the forms of earth building used by civilizations of varying technical development, rammed earth is the most durable. After World War II it was studied as an economic technique for underdeveloped regions. Its use is limited to soils with high sand and low clay contents, 70%:30% being a usual proportion, with the sand graded to various particle sizes. The mix, with about 10% water added, is compacted in molds by ironheaded rammers weighing 5 to 20 lb. (See SOIL MECHANICS.)

The mold may be a box for individual wall blocks or a long wooden form, about 2 ft. high, consisting of two sides separated by spacer bolts, which is placed on the wall. The soil is rammed into this in about 3-in. layers, the form being removed when it is filled and again superimposed. Special angle, 'T' and stopped-end forms are used for corners, junctions and openings. Roller-mounted forms, pneumatic rammers, and hydraulic, mass-production block presses have been used.

The moisture content at compaction is critical to the ultimate strength and shrinkage of the wall, the optimum falling between narrow limits. Compressive strengths vary from 100 lb. per square inch to 500 lb. per square inch, while densities average 130 lb. per cubic foot and increase with sand content. Minimum wall thicknesses are usually 12 in.; this mass results in a high thermal capacity. The time lag in its temperature changes maintains uniform internal conditions in climates with large day-night temperature variations. The wall surface is often given increased weather resistance with plaster, bitumen or linseed-oil treatment.

Strength and weather resistance can be increased by small additions of soil stabilizers. Portland cement and bitumen are the most commonly used.

(T. A. M.)
RAMÓN Y CAJAL, SANTIAGO (1852–1934), Spanish histologist, who shared with Camillo Golgi (*q.v.*) the 1906 Nobel Prize for Medicine in recognition of their work on the structure of the nervous system, was born May 1, 1852, at Petilla de Aragón. He was a wild youth and so backward in his studies that his father, a struggling country surgeon, took him away from school and apprenticed him first to a barber and then to a cobbler. He was eventually allowed to enter the medical school of Saragossa (Zaragoza) and after obtaining his medical licence in 1873 served for a year as an army surgeon in Cuba.

In 1875 he was appointed an assistant in the Saragossa medical faculty and having at last found his natural bent he devoted himself to the study of anatomy. In 1877 he was promoted extraordinary professor and two years later he became director of the medical museum of Saragossa University. In 1883 he went to the University of Valencia as professor of descriptive anatomy and in 1887 to the University of Barcelona as professor of histology and pathological anatomy. From 1892 until his retirement in 1922 he held the chair of histology and pathological anatomy at the University of Madrid. He died on Oct. 17, 1934.

Ramón y Cajal won worldwide fame by his researches on neuroanatomy. Having adapted Golgi's silver-stain method of staining nervous tissue, he began to explore the then unknown world of the cerebellum and the cerebrum and to publish the results of his researches in a flood of books and papers. One of his most fundamental achievements was the establishment of the neuron or nerve cell as the basic unit of the nervous system. Among his best-known writings are the great *Manual de histología normal y técnica micrográfica* (1889; English translation, 1933), *Textura del sistema nervioso del hombre y de los vertebrados* (1897–1904), and *Estudios sobre la degeneración y regeneración del sistema nervioso* (1913–14; English translation 1928). He was also the author of a fascinating autobiography, *Recuerdos de mi vida* (1901; English translation, 1937), and of the earlier *Charles de Café* (1920), containing anecdotes and thoughts on a wide variety of subjects.

See D. F. Cannon, *Explorer of the Human Brain: the Life of Santiago Ramón y Cajal* (1949). (W. J. Bp.)

RAMPOLLA (DEL TINDARO), MARIANO (1843–1913), Italian cardinal who, as secretary of state for the last 16 years of Pope Leo XIII's reign, collaborated with the pope in his efforts to reconcile the French Church to the republican regime and to advance the cause of international peace. Born on Aug. 17, 1843, at Polizzi in Sicily, he completed his studies at the Capranica College in Rome, took holy orders, and was trained for diplomacy at the College of Ecclesiastical Nobles. In 1875 he was appointed counselor to the papal nunciature in Madrid. Recalled to Rome in 1877, he served on the Congregation for the Propagation of the Faith before being sent back to Madrid as nuncio (1882–87). He was created cardinal on March 14, 1887, and two months later Leo XIII appointed him secretary of state.

Alive to the political and social realities of his age, Rampolla assembled the ideas for the encyclical *Rerum novarum* of 1891 (see LEO XIII). On Leo's death (1903) his prestige stood high and he was widely expected to be the next pope. Germany and Austria-Hungary, however, objected to his pro-French attitude, in which they saw political motives; and at the conclave, when Rampolla, on the first scrutiny, had received 29 votes, the cardinal bishop of Cracow, Jan Puzyna, announced that his sovereign, the Austrian emperor Francis Joseph, would exercise his veto against him. Pope Pius X, who subsequently abolished the right of veto, made Rampolla head of the Congregation of the Holy Office. The cardinal died in Rome on Dec. 16, 1913.

See G. Sinopoli di Giunta, *Il Cardinale Mariano Rampolla* (1923).

RAMPUR, a city and district in the Rohilkhand division of Uttar Pradesh, India. The city, formerly the capital of the Rampur princely state and now the headquarters of the district, stands on the left bank of the Kosi River, 115 mi. (185 km.) E of Delhi. Pop. (1961) 135,407. It is a centre for damask, light steel work, pottery, and sugar manufacture. Raza College is affiliated to

Agra University; the library contains a fine collection of Oriental manuscripts.

RAMPUR DISTRICT (area 895 sq.mi. [2,318 sq.km.]; pop. [1961] 701,537) corresponds with the former princely state of Rampur (Gwalior residency). After India's independence in 1947, Rampur was centrally administered from Delhi through a commissioner before being merged into Uttar Pradesh on Dec. 1, 1949. The district is a level and fertile plain sloping to the south and southeast. It is drained in the north by the Kosi and Nahul rivers and in the south by the Ramganga. Wheat, maize (corn), rice, gram, and sugarcane are the chief crops. Shahabad (south) and Tanda (northwest) are the main towns besides Rampur.

The Rohilla Pathans established power over this area in the 18th century. They were subjugated by the nawab of Oudh with help from Warren Hastings, but one of them, Faizullah Khan, was allowed to keep Rampur, and the last ruling family was descended from him.

(S. S. Bh.)

RAMSAY, ALLAN (c. 1685–1758), Scottish poet whose publications made available to Robert Fergusson and Robert Burns the work of earlier Scottish poets. He also preserved, though in a polished and possibly inferior form, many Scottish folk songs and with them their tunes. His own poetry varies with some uncertainty of tone and taste between Augustan polish and the rougher freshness of Scottish vernacular poetry. Born at Leadhills, Lanarkshire, Oct. 15, 1684 or 1685, he was probably educated at the parish school of Crawford, and about 1700 left for Edinburgh, where in 1704 he was apprenticed to a wigmaker. He became a burgher in 1710, establishing himself as a wigmaker, and married Christian Ross in 1712. He was one of the founders of the literary Easy Club in 1712, adopting the pseudonym first of Isaac Bickerstaff and later of Gawin Douglas. He began by writing occasional verse, the first piece of which was published in 1713; some of his poems were published as broadsheets. In 1718 he published a version of the old Scots poem, *Christ's Kirk on the Green*, with additional verses of his own, and a collection, *Scots Songs*; and he turned bookseller. The success of these ventures prompted him to publish his collected poems in 1720, and in 1721 to issue them as a quarto volume by subscription. The subscription brought in 400 guineas, and a similar edition of volume two of his *Poems* in 1728 was an even greater success. He thus achieved financial independence and about 1740 was able to retire to his house on Castle Hill.

Meanwhile he had issued *The Ever Green* (2 vol., 1724) in which he was inspired by nationalist feelings to edit some of the older Scots literature; following the example of James Watson's *Choice Collection* (1706–11) he transcribed poems of Dunbar, Henryson, and others from the 16th-century Bannatyne manuscript. *The Tea-Table Miscellany* (4 vol., 1724–37), in some editions subtitled "A Collection of Choice Songs Scots and English," contains some by Ramsay and some by his friends, several genuine folk ballads and songs, and some 17th-century verse. In 1725 he published his dramatic pastoral *The Gentle Shepherd*, which had immense popularity. Ramsay wrote little afterward, though new editions of his work continued to appear during his lifetime.

His other activities were to set up what was apparently the first circulating library in Great Britain (before 1728), to encourage the fine arts, and against opposition to help attempts to set up a theatre in Edinburgh. In 1736 he opened a theatre in Car-rubber's Close, but this was closed by authority a year later.

Ramsay's place in literary history owes less to his merits as a poet than to his immense influence on two much greater men, Fergusson and Burns.

BIBLIOGRAPHY.—Ramsay's *Works*, ed. by Burns Martin and J. W. Oliver, 4 vol. (1951–); A. Gibson, *New Light on Allan Ramsay* (1927); B. Martin, *Allan Ramsay, a Study of His Life and Works* (1931).

(M. J. C. H.)

RAMSAY, ALLAN (1713–1784), Scottish portrait painter, the son of Allan Ramsay, author of *The Gentle Shepherd*, was born in Edinburgh on Oct. 13, 1713. After rudimentary training in Edinburgh he went to London and worked under the Swedish portrait painter Hans Hysing (1734), but his style was really formed by his studies in Italy (1736–38) under Francesco Im-

periali and Francesco Solimena. On settling in London he soon became popular, although George Vertue in 1739 noted with distress that his style differed from the "valuable Manner" of Sir Godfrey Kneller and others and was "rather lick't than pencilled" (i.e., his brushwork was smooth, not free).

His "Dr. Mead" of 1747 (Foundling hospital, London) is in the Italian grand manner, preceding Sir Joshua Reynolds' grand portraits by several years; but perhaps the rise of Reynolds induced Ramsay to return to Italy in 1755-57. During the 1760s Ramsay painted little but royal images on government commission: most of this hack work was done by assistants and Ramsay devoted himself to political pamphleteering, classical studies and conversation—Dr. Johnson said to Boswell: "I love Ramsay. You will not find a man in whose conversation there is more instruction, more information, and more elegance . . ." Ramsay died at Dover on Aug. 10, 1784, while returning from his fourth visit to Italy.

Ramsay's best works are in the National gallery of Scotland, including important drawings, and the National Portrait gallery, Edinburgh; but there are also pictures in London (National Portrait gallery and Tate gallery) and Liverpool. His "Youth With Cap and Gown" was acquired by the Huntington gallery, San Marino, Calif., and his portrait "Mary Lillian Smith" by the Ringling museum, Sarasota, Fla.

See Alastair Smart, *Life and Art of Allan Ramsay* (1952).

(P. J. MY.)

RAMSAY, SIR WILLIAM (1852-1916), British chemist who discovered the elements known as noble gases, was born in Glasgow, Scot., on Oct. 2, 1852. From 1866 to 1870 he studied in his native city. He then went to Heidelberg and studied under Robert Wilhelm Bunsen and in 1871 went to work under R. Fittig at Tübingen. In 1872 he became assistant in the Young laboratory of technical chemistry at Anderson's college, Glasgow. He received his Ph.D. from Tübingen in 1873 and from 1874 was tutorial assistant in the university. In 1880 he was appointed to the chair of chemistry at University college, Bristol, and made principal in the following year. In 1887 he succeeded A. W. Williamson as professor at University college, London, a position from which he resigned in 1913. He was awarded the Davy medal of the Royal society in 1895 and the Nobel prize for chemistry in 1904. He was made a knight commander of the Bath in 1902. He died at High Wycombe, Buckinghamshire, on July 23, 1916.

Ramsay's earliest investigations covered a wide field—from a new bismuth mineral to the physiological action of certain alkaloids—in the course of which he showed that the alkaloids are related to pyridine, which he synthesized from acetylene and prussic acid in 1876. Later he specialized definitely in inorganic and physical chemistry. With Sidney Young (1857-1937) and others he investigated the critical state, the relationship between vapour pressure and temperature and other properties of liquids (Ramsay-Young rule). In 1887 he found that absolutely dry ammonia and hydrogen chloride do not combine.

With J. Shields (1869-1920) he verified the Eötvös law of the constancy of the rate of change of molecular surface energy with temperature, and obtained evidence concerning the molecular complexity of certain liquids. In 1892 Lord Rayleigh asked for suggestions from chemists to account for the difference between the densities of chemical and atmospheric nitrogen, and Ramsay became interested in the problem. He at once predicted that an unknown heavy gas was present. Rayleigh preferred to believe that a heavy modification of nitrogen, analogous to ozone, was the disturbing factor. Ramsay devised methods for removing oxygen and nitrogen completely from air and found that there was present in addition a small quantity of a hitherto unknown gas. In Aug. 1894 Ramsay and Rayleigh announced the discovery of this new gas, afterward called argon (*q.v.*), present to the extent of almost 1% in the atmosphere. Its presence had been indicated as early as 1785 by Henry Cavendish. The high density of this gas accounted for the atmospheric nitrogen having a greater density than the chemical variety. In 1895, while searching for new sources of argon, Ramsay heated the mineral cleveite with acid and obtained a gas which gave a spectrum identical with that of helium (*q.v.*), detected in the sun by Sir J. N. Lockyer and Sir E. Frankland in 1868.

In this way helium was first obtained, but it was later found to be present in the air to the extent of about 1 part in 250,000.

Both helium and argon were then believed to be inactive chemically and so were called the inert gases. They fitted into the periodic system although no provision had been made for chemically inactive elements. Furthermore, a study of their position in the periodic table led to the belief that at least three more such gases should exist. Ramsay, with M. W. Travers, found them in 1898 in liquid air residues from which oxygen and nitrogen had been removed; they were called neon, krypton and xenon (*qq.v.*) and were found to be present in the air only to an extremely minute extent (e.g., xenon, 1 part in 170,000,000). Ramsay next turned to radioactivity, since he noted the association of helium with radioactive minerals. With F. Soddy (*q.v.*) he found in 1903 that helium was continuously produced as a disintegration product of radium emanation. This discovery led to the transmutation theory and its important consequences. In 1910 Ramsay obtained a small quantity of radium, and with Whytlaw Gray he was able, as a result of a wonderful piece of experimental work, to determine the density, and incidentally the atomic weight, of about one three-millionth part of a cubic inch of radium emanation. The atomic weight showed that this gas was the last of the noble-gas series. It was called niton and is now mainly known as radon (*q.v.*) or emanation. Ramsay thus has the unique fame of discovering a whole family of elements.

Ramsay's works include: *A System of Chemistry* (1891); *The Gases of the Atmosphere* (1896; 4th ed., 1915); *Modern Chemistry*, 2 vol. (1901); *Essays Biographical and Chemical* (1909); *Life and Letters of Joseph Black* (1918); *Elements and Electrons* (1913); *Introduction to the Study of Physical Chemistry* (1904).

(R. E. O.)

RAMSDEN, JESSE (1735-1800), English astronomical instrument maker, whose celebrated five-foot vertical circle, made for the observatory at Palermo, Italy (1789), quickened the tendency of divided circles to supersede quadrants in observatories toward the end of the 18th century.

He was born at Salterhebble near Halifax, Yorkshire, probably on Oct. 6, 1735. After serving his apprenticeship with a cloth-worker in Halifax, he went in 1755 to London, where in 1758 he was apprenticed to a mathematical instrument maker. About four years afterward he started his own business and secured a great reputation with his products. He died at Brighton on Nov. 5, 1800. Ramsden specialized in divided circles; the Palermo vertical circle was used by the monk-astronomer G. Piazzi in constructing his well-known catalogue of stars.

RAMSES (RAMESESSES, Egyptian RAMESSU) was the name of (1) an ancient city and district in northeastern Egypt and (2) a line of pharaohs of the 19th and 20th dynasties (1320-c. 1085 B.C.).

The city was one of the store-cities built by the Hebrews of the Oppression. It later became the starting point of the Exodus. It has been plausibly identified with Pi-Ramessu (Per-Rameses), the residence-city of the Ramesside pharaohs, which is placed by some scholars at Tanis (modern San al Hajar) in the eastern Nile Delta and by others at Qantir farther south.

There were 11 pharaohs of this name:

RAMSES I (1320-1318 B.C.), the founder of the line, came to the throne as an old man. He was one of the generals who completed the overthrow of the Atonist regime established by Ikhnaton.

RAMSES II (1304-1237 B.C.) is often known as Ramses the Great because of the size and ubiquity of his monuments, of which he erected hundreds throughout Egypt and Nubia during his long reign. They included temples decorated with grandiose scenes of his victories, obelisks, and colossal statues of himself. His cartouches were carved deeply upon existing monuments. He also founded many towns and built fortresses on the Libyan frontier of Egypt; in the eastern delta, whence his family had sprung, a number of palaces arose, of which the most splendid was Pi-Ramessu

("the house of Ramses"). He warred for 17 years against the Hittites, and his greatest encounter with them at Kadesh (q.v.; 1299 B.C.) was celebrated as a great victory on the walls of a number of his temples. A treaty of nonaggression in his 21st year was sealed by marriage with a Hittite princess. Among the temples which he scattered along the banks of the Nile in Nubia, the grandeur of Abu Simbel (q.v.) with its huge seated colossi must have made an awesome impression on the superstitious Nubians.

RAMSES III (1198–1166 B.C.) modeled himself in many respects upon his illustrious namesake. He averted a threat of invasion from the Libyans and repulsed the more serious onslaught of a confederation of Mediterranean raiders. He did much to restore Egypt's prosperity. He was assassinated in a palace intrigue.

RAMSES IV–XI ruled successively from 1166 to c. 1085 B.C. Their reigns were marked by a progressive weakening of the central authority and brought the 20th dynasty to an inglorious end. See also EGYPT: History. (M. S. Dr.)

RAMSEY, ARTHUR MICHAEL (1904–), archbishop of Canterbury, who combines firm High Church principles with a generous understanding of other traditions and is active in promoting Christian unity, was born on Nov. 14, 1904, at Cambridge where his father was a fellow of Magdalene College. From Repton School (where his headmaster was Geoffrey Fisher) he went to Cambridge as scholar of Magdalene, obtained first-class honours in theology and was president of the Union. After attending Cuddesdon Theological College he became curate of Liverpool Parish Church (1928–30), subwarden of Lincoln Theological College (1930–36), lecturer of Boston (Lincolnshire) Parish Church (1936–38), and vicar of St. Benet's, Cambridge (1939–40). Having made his mark as a teacher and published an influential book, *The Gospel and the Catholic Church* (1936), he became canon of Durham and professor of divinity in Durham University (1940), and then regius professor of divinity at Cambridge (1950–52), before returning to Durham as bishop. In 1956 he was translated to York as archbishop and in 1961 to Canterbury. In March 1966 in a historic encounter—the first formal meeting of a pope and an archbishop of Canterbury since the severance of the Church of England from the papacy in 1534—Ramsey and Pope Paul VI exchanged the "kiss of peace" and conferred privately on issues of concern to the two churches.

As a theologian, Ramsey has been engaged chiefly in the study of the New Testament and in the broad exposition of Christian doctrine. His publications include *The Resurrection of Christ* (1944), *The Glory of God and the Transfiguration of Christ* (1949), *F. D. Maurice and the Conflicts of Modern Theology* (1951), *From Gore to Temple* (1960), and *Introducing the Christian Faith* (1961). (S. L. G.)

RAMSEY, an agricultural market town and urban district of Huntingdonshire, Eng., lies on the southwestern border of the Fens, 12 mi. (19 km.) NNE of Huntingdon by road. Pop. (1961) 5,697. The town grew up around the Benedictine abbey founded in A.D. 969 by Duke Aethelwine. Ramsey was a "mitred" abbey, i.e., its abbot was entitled to a seat in Parliament, and it was granted freedom from ecclesiastical and secular control and other privileges before the Conquest. It was a seat of learning and its library of Hebrew books was famous long before Oxford and Cambridge. After the Dissolution its demesnes were granted to Sir Richard Cromwell. In 1938 a new building had been erected at the abbey for the grammar school (founded 1656). A statue, supposedly of Ailwyn, once in the abbey, has been placed in the gatehouse. The Church of St. Thomas à Becket is mostly Norman; the tower, added in 1673, is of stone from the abbey. An oak lectern carries a chained copy of Dean Thomas Comber's (1645–99) book on the Common Prayer, and in the church is also a blackletter copy of Erasmus' paraphrase of the New Testament.

RAMSGATE, a municipal borough, holiday resort, seaport, and limb of the Cinque Port of Sandwich, in the Isle of Thanet parliamentary division of Kent, Eng., 18 mi. (29 km.) NNE of Canterbury by road. Pop. (1961) 36,914. Area 5.7 sq.mi. (15 sq.km.). Ramsgate was originally a small fishing hamlet and is mentioned in a charter of Charles II as being under the jurisdiction

of Sandwich, of which town Ramsgate became a limb or liberty within the confederation of the Cinque Ports in the reign of Henry VII. From that time Ramsgate developed as a seaport. The present harbour, on which George IV conferred the royal style or title, was built in the mid-18th century, and from that time substantial trade was developed with Baltic and other continental countries. Ramsgate became noted as a health resort and is now one of the most popular seaside holiday towns on the coast of Kent. The port has good facilities for commercial traffic and is a centre for motor cruisers and yachts. The development of the Kent coal-field during the 20th century brought additional trade to Ramsgate, the nearest pits being Betteshanger and Chislet about 10 mi. away. Small light industrial factories have been established in and near the town. Ramsgate has many historical associations. Cliffsend on the western extremity of the borough is the reputed landing place of Hengist and Horsa in A.D. 449 and of St. Augustine in A.D. 597. At Pegwell Bay rests the "Hugin," replica of a Viking ship rowed over from Denmark in 1949. St. Laurence Church dates from early Norman times. A. W. N. Pugin is buried in the Roman Catholic Church of St. Augustine, which he built. The town possesses a well-known boys' school (St. Lawrence College) and two grammar schools. Charter flights are available at the municipal airport.

RAMUS, PETRUS, the latinized form of the name of the Frenchman PIERRE DE LA RAMÉE (1515–1572), the most famous logician of the 16th century. Born to the Catholic faith, of an impoverished family of noble ancestry, at the small French village of Cuts in the Vermandois District of Picardy, he died 57 years later in Paris at the hands of hired assassins—one of the most celebrated Protestant victims of the Massacre of St. Bartholomew's Day. Two years after Ramus' birth, Luther posted his theses on the door of the Castle church at Wittenberg, and that event, which exploded into the Protestant Reformation, turned the 16th century into an age of intense religious dispute and military violence. It was Ramus' destiny to be chiefly remembered for the part he played in providing that age with its most influential theory of controversy.

Educated at Cuts and subsequently at the Collège de Navarre, in Paris, where he earned his way by working as servant for a wealthy schoolmate, Ramus in 1536 became master of arts, his Latin commencement disputation being a defense of the thesis *Quaecumque ab Aristotele dicta essent, commentitia esse*. Though 18th- and 19th-century scholarship construed this thesis to mean that "everything which Aristotle had said is false," in fact *commentitia* involves not so much the idea of falsehood as that of unnatural or contrived organization, and accordingly Ramus is now accepted less as an opponent of Aristotle than as a reorganizer and simplifier of Aristotelian doctrine. Putting his thesis into immediate effect, Ramus taught a reformed version of Aristotelian logic at the Collège du Mans, in Paris, and later at the Collège de l'Ave Maria, where he worked with Audomar Talaeus (Omer Talon; c. 1510–62), who under Ramus' influence reformed Ciceronian rhetoric upon the principles applied by Ramus to the rearrangement of Aristotle's *Organon*. The innovations of Ramus and Talaeus so provoked the Peripatetic (orthodox Aristotelian) philosophers at the University of Paris that they induced Francis I to issue a decree on March 10, 1544, suppressing Ramus' books on the reformed logic and forbidding him to teach that subject. But Ramus was allowed to turn to the teaching of mathematics and rhetoric at a new post at the Collège de Presles. Thanks to the intercession of the cardinal Charles de Lorraine, one of Ramus' powerful friends, the ban against his teaching logic was lifted in 1547 by Henry II, and in 1551 he was appointed regius professor of philosophy and eloquence at the Collège de France. Around 1561 he was converted to Protestantism, and the last years of his life were marked by a mounting persecution from his academic and ecclesiastical enemies at home and by his growing fame as a logician abroad. On Aug. 26, 1572, two days after the outbreak of the Massacre of St. Bartholomew's Day, he was murdered in Paris.

Ramus' logic neglected the traditional role which that discipline had played as a method of inquiry, and emphasized instead an equally traditional view that logic is the method of disputation.

Thus Ramus identified logic with dialectic and made it the art of disputing well, its two parts being invention and disposition (divisions to Ramus were characteristically dichotomous). Invention was the process of discovering proofs in support of any thesis under examination. It consisted in canvassing the ten places in which arguments dwell: causes, effects, subjects, adjuncts, opposites, comparatives, names, divisions, definitions, and witnesses. Disposition taught how the materials of invention should be arranged for presentation either in a single proposition, or in a syllogism, or in an entire discourse.

In speaking of the arrangement of discourses, Ramus evolved his famous theory of method. To him method was of two kinds. The first he called the method of nature, by which discourses were arranged for men of learning in a descending order of generality by a process of defining and dividing wholes and parts and subparts until nothing could be defined or divided further. The second kind of method he called the method of prudence. It consisted in arranging discourses for the populace by devices exemplified in oratory and poetry.

For the particular contribution of Ramus to the treatment of the syllogism, see *LOGIC, HISTORY OF: Modern Logic*.

While Ramus was perfecting dialectical theory, Talaues rewrote Ciceronian rhetoric, depriving it of invention and disposition, since these were parts of dialectic, and confining it to style and delivery, that is, to the tropes and figures on the one hand, and to voice and gestures on the other.

Ramus' dialectic and Talaues' rhetoric had an enormous vogue in Europe throughout the late 16th and early 17th centuries. Then these complementary reforms collapsed, as logic under one set of auspices turned back toward traditional Aristotelianism and under another forward toward the inductive sciences, while rhetoric at first reverted to a traditional but outmoded Ciceronianism and then deliberately fragmented itself into the study of the tropes and figures and into the later preoccupation with voice and gestures under the auspices of the elocutionists. In respect to logic, Ramus' influence was powerful but transitory. His influence upon rhetoric, however, was a near disaster, as that discipline was reduced to the mere externals of verbal ornament and artful vocalization, and no longer had a vital connection with the meaning and form of discourse. Not until the late 18th century did rhetoric begin to define a new set of relations to literary theory.

Ramus' most celebrated works were *Dialecticae Partitiones* (1543), *Aristotelicae Animadversiones* (1543), *Dialectique* (1555), and *Dialecticae Libri Duo* (1556). His writings on other subjects were voluminous.

For the influence of Ramus in the English-speaking world see Perry Miller, *The New England Mind: the Seventeenth Century* (1939); W. S. Howell, *Logic and Rhetoric in England, 1500-1700* (1956).

(W. S. H.)

RAMUSIO, GIOVANNI BATTISTA (1485-1557), Italian geographer, who compiled a famous travel collection, *Delle Navigazioni et Viaggi*, was born at Treviso on July 20, 1485. He entered the Venetian public service, becoming secretary of the Senate in 1515, and of the Council of Ten in 1533. He died at Padua on July 10, 1557.

Ramusio had witnessed from his boyhood the great discoveries in the East and West, and geography became his chief study. He seems to have begun the collection of material about 1520, at the suggestion of the humanist Girolamo Fracastoro, and he was tireless in searching for geographical narratives and documents. Among Ramusio's principal collaborators and correspondents were Andrea Navagero, Cardinal Pietro Bembo, Fracastoro, and the cartographer Giacomo Gastaldi.

The arrangement of the *Navigazioni* is regional. Two volumes only, from the press of L. A. Giunti at Venice, were published in Ramusio's lifetime: volume i (Africa) in 1550, volume iii (America) in 1557. Volume ii (Asia) appeared in 1559 and was the first to name Ramusio as the editor. Four later editions of volume i were issued; three of volume ii; and two of volume iii. Among the important texts which are uniquely found in the *Navigazioni* are Ramusio's version of Marco Polo and the *Descrittione del*

l'Africa (*Description of Africa*) by Leo Africanus.

See S. Grande, "Le relazioni geografiche fra P. Bembo, G. Fracastoro, G. B. Ramusio e G. Gastaldi," *Memorie della società geografica italiana*, vol. xii, pp. 75-92 (1905).
(R. A. SN.)

RAMUZ, CHARLES FERDINAND (1878-1947), French-Swiss novelist, one of the most powerful and original writers in the history of Swiss literature, was born at Lausanne on Sept. 24, 1878, and as a young man spent several years in Paris. Ramuz took most of the material for his novels from the vine-growing Alpine peasants of the Valais and the Vaud. He did what Jeremias Gotthelf (see *BITZIUS, ALBERT*) did for the Emmental, giving universal significance to a limited region. Whereas Gotthelf achieved this by creating a unified world based on his own religious and moral philosophy, Ramuz worked like a painter, turning the half-concealed manifestations of the natural law into human symbols. Both Gotthelf and Ramuz, however, built up their own poetic language from a stylization of the regional dialect. The peasant as Ramuz sees him is, like Racine's kings, free from both social convention and intellectual and psychological complexity, "the prey of God," given over to human passions and destiny and therefore, like the Greeks, peculiarly suited to tragedy.

Ramuz' work was long a matter of controversy. His language belongs to a so exclusively French civilization that it was some time before it won more general critical recognition. He then came to be accounted one of the most creative minds in modern French literature, the power and purity of his vision and the originality yet propriety of his forms winning him ever increasing recognition. He died at Pully, near Lausanne, on May 23, 1947.

His works include: *Le Petit Village* (1903); *Aline* (1905); *Jean-Luc persécuté* (1909); *Le Règne de l'esprit malin* (1914; Eng. trans., *The Reign of the Evil*, 1922); *La Guérison des maladies* (1917); *Les Signes parmi nous* (1919); *Salutation paysanne* (1921); *Passage du Poète* (1923); *La Grande Peur dans la montagne* (1925); *La Beauté sur la terre* (1927; Eng. trans., *Beauty on Earth*, 1929); *Farinet* (1932); and *Le Garçon savoyard* (1936). A collected edition, in 23 volumes, was published (1940-54).

(W. GR.)

RANA, a dynasty of hereditary prime ministers of Nepal during the 19th-20th centuries. The title of Rana or Ranaji was granted to Jung Bahadur (q.v.), the first of these prime ministers, during his tenure of office (1846-77). The title came to be invariably suffixed to his name as also to that of his brothers and their descendants. Having been appointed hereditary prime minister, and believing it essential for the security of the state that he should be succeeded by a fully adult and capable man, he devised an order of succession by which the office passed not from father to son but from brother to brother within the family and then in the second generation to the sons of all his brothers in order of age and so on. Thus when he died he was succeeded by his next eldest brother, Rana Udip Singh. Jung Bahadur's wild and undisciplined sons plotted to seize the office of prime minister for themselves and as a result were exiled. The succession passed eventually to the sons of Dhir Shumsher, one of Jung Bahadur's younger brothers. The family then adopted the suffix of Shumsher Jung Bahadur Rana. In succession the prime ministership passed from one to the other of Dhir Shumsher's sons. Chandra Shumsher (prime minister 1901-29) was a man of wisdom who introduced many reforms including the abolition of slavery. Joodha (1932-45), the last surviving son of Dhir Shumsher, was faced on his succession by a dynastic crisis. According to Jung Bahadur's rule, succession could pass only to the sons of a senior wife, but both Maharaja Bir Shumsher and Maharaja Bhim Shumsher had placed sons by junior wives on the roll. In order to avoid an outright conflict between the sons of senior and junior wives, Joodha reverted to Jung Bahadur's rule, struck the sons of junior wives off the roll, and banished them from Katmandu. The family was then divided among itself, and its system of rule was fast becoming an anachronism. Joodha was succeeded by Padma, son of Maharaja Bhim Shumsher and the first of the next generation. Padma himself retired in 1948 and was succeeded by Mohun, the last of the hereditary prime ministers, who retired in 1951. See also *NEPAL: History*.
(R. R. P.)

RANADE, MAHADEO GOVIND (1842–1901), Indian judge, social reformer, and author, who helped in the foundation of the Indian National Congress and exercised an important influence on the moderate side, was born on Jan. 18, 1842, at Niphad, in the Nasik District near Bombay, of a Chitpavan Brahman family. He was educated at Elphinstone College, Bombay, and graduated from Bombay University in 1862. A distinguished judicial career under the Bombay government culminated in his appointment to the High Court in 1893. He was also appointed to the government of India's committee on official expenditure in 1886 and was made a Companion of the Order of the Indian Empire for his services in that connection.

Ranade took a leading part in social reform movements and in this respect was opposed by those extreme nationalists who thought that social reform should be subordinated to political activity. He was also a leading member of the Prarthana Samaj of Bombay, a reformist Hindu sect resembling the Brahmo Samaj (*q.v.*) of Bengal. His *Rise of the Maratha Power* (1900) was of importance in stimulating interest and pride in Maratha history, in spite of his tendency to praise the Maratha ruler Sivaji's system of government by likening it to that of the British, or the religious revival of that time by likening it to the Protestant Reformation in Europe. He died at Bombay on Jan. 16, 1901.

See J. Kellock, *Mahadev Govind Ranade: Patriot and Social Servant* (1926). (K. A. B.)

RANCÉ, ARMAND JEAN LE BOUTHILLIER DE (1626–1700), Cistercian monk, founder of the reformed Cistercians called Trappists, was born at Paris on Jan. 9, 1626, of a noble family. At an early age he became commendatory abbot of the Cistercian abbey of La Trappe, in Normandy. After brilliant studies, he distinguished himself as a *littérateur* and orator; he shone intellectually in the assembly of the French clergy in 1655. Up to 1657 Rancé had led a worldly life. In that year began his conversion, which was completed in 1660. He disposed of his possessions, resigned his benefices, and became in 1664 regular abbot of La Trappe, in which position he did all he could to reform the Cistercian order. One of his measures was an attack on learning, in his *Traité de la sainteté et des devoirs de la vie monastique* (1683), as being contrary to the spirit of monastic life, which he believed should be confined to prayer and manual labour; this led to a long-drawn-out quarrel with J. Mabillon. In 1678 Rancé obtained papal approval of his reform, which spread widely. He died at Soligny-la-Trappe on Oct. 27, 1700. See also CISTERCIANS; *Trappists*; LA TRAPPE, NOTRE DAME DE.

See P. Le Nain, *Vie de Rancé* (1715); H. Brémond, *The Thundering Abbot* (1930). (E. A. R.; X.)

RANCHI, a city and district in the Chota Nagpur division of Bihar State, India. The city, headquarters of the district and division, lies about 2,100 ft. (640 m.) above sea level and 133 mi. (214 km.) NW of Jamshedpur by rail and road. Pop. (1961) 140,253. The town straggles along the excellent roads which converge from several directions. It has a cantonment, a radium institute, and two large mental hospitals. Its seven colleges include a medical and an agricultural college, and in July 1960 the city became the seat of Ranchi University with jurisdiction over Chota Nagpur division. The establishment there in the 1960s of the National Coal Development Corporation of India and the Hindustan Steel Company and the erection of a large heavy machine tool factory gave impetus to the city's growth. Ranchi is midway between the coal and iron belts of the Chota Nagpur Plateau and lies on a narrow-gauge railway from Muri to Lohardaga, but because of its growing industrial importance it was being linked by a broad-gauge line from Muri to Roorkela in the 1960s.

RANCHI DISTRICT has an area of 7,047 sq.mi. (18,251 sq.km.) and a population (1961) of 2,138,565. Physically, in the extreme northwest, it consists of an elevated basaltic laterized plateau (3,600 ft.) from which bauxite is exploited, and a rejuvenated 2,000-ft. (610 m.)-high undulating, deforested peneplain, with extensive terraced cultivation. The edges of this peneplain are steep and forested. The principal rivers are the Subarnarekha, Sankh, and North and South Koel. Rice is the predominant crop. There is a cement factory at Khelari; shellac is also manufactured

and myrobalans are processed. More than half of the inhabitants are tribal peoples, the most important of which are the Mundas and Oraons. The Christian population totaled 422,030 in 1951. There are sanatoriums for lepers and tuberculous patients in the district. (E. A. H.)

RANDALL, JAMES RYDER (1839–1908), U.S. journalist and poet, best known as author of the lyrics of "Maryland! My Maryland!" was born in Baltimore, Md., on Jan. 1, 1839. Educated at Georgetown College, Washington, D.C., he became professor of English literature at Poydras College at Pointe-Coupée, La., in 1860 where he was when the Civil War broke out. The attack made by citizens of Baltimore upon Massachusetts and Pennsylvania troops as they passed through the city was the occasion of his writing "Maryland! My Maryland!" first published in the *New Orleans Delta*, April 1861. First sung by Hetty Cary to the classic melody of "Lauriger Horatius," it became a rallying song of the Confederacy and later a national favourite. After the war Randall became associate editor of the *Augusta* (Ga.) *Constitutionalist*. He was later Washington correspondent for a number of southern papers. He died in Augusta on Jan. 14, 1908. His *Poems* were published posthumously in 1910.

RANDERS, a town of Jutland, Den., capital of Randers amt (county), lies on the Gudenaa River where it widens into the Randers Fjord, an inlet of the Kattegat, 37 mi. (59 km.) NNW of Aarhus by rail. Pop. (1960) 42,238. Some medieval merchants' houses have survived and St. Martin's Church (1490), the Holy Ghost Hospital (1510), and the town hall (1768) are noteworthy. Randers is on the main railway from Fredericia to Aalborg and is the commercial centre of a prosperous agricultural region. Railway rolling stock, rope, yeast, beer, textiles, gloves, furniture, tiles, milk powder, and agricultural machinery are produced. First mentioned in 1086, Randers obtained town privileges in 1302. The tyrant Count Gerhard III of Holstein was assassinated there in 1340 by the Danish national hero Niels Ebbesen.

RANDERS AMT consists of lowland country covering the Djursland Peninsula and extending northward to the Mariager Fjord. Area 952 sq.mi. (2,466 sq.km.). Pop. (1960) 170,231. After Randers, the chief towns are Grenaa, Aalborg, and Mariager. There is an international airport at Tirstrup, 25 mi. (40 km.) ESE of Randers. (K. O.)

RANDFONTEIN, a town of the Transvaal, Republic of South Africa, lies 28 mi. (45 km.) W of Johannesburg by road and rail at 5,820 ft. (1,774 m.) above sea level. Pop. (1960) 41,499, of whom 13,647 were Europeans. Established as a separate municipality in 1929, in the 1960s it was undergoing considerable industrial expansion on account of its central position on the Witwatersrand. Notable buildings include the town hall (1930) and the Jewish synagogue (1958), and the town has two high schools and a technical college. Within its municipal area are Riebeeck Lake (with a swimming pool of Olympic standards) and Robinson Lake, which is heated for all-year swimming by a flume from the mine power station. Being on the main road and railway network Randfontein has good communications with the rest of the Transvaal and with other parts of the republic. There is an airfield near the town. The chief industries are mining, engineering, food processing, and textiles. (C. J. J.)

RANDOLPH, EDMUND JENNINGS (JENINGS) (1753–1813), Virginia lawyer who played an important role in drafting and ratifying the U.S. Constitution and served as attorney general and later secretary of state in Washington's cabinet, was born Aug. 10, 1753, in Williamsburg, Va. After attending William and Mary College he studied law in the office of his father, who was then the king's attorney in the colony. The approach of the American Revolution caused a split in the family: the father, with his wife and daughters, left for England in 1775 while Edmund threw in his lot with the rebellious colonists.

The young lawyer served briefly as an aide to General Washington in the siege of Boston and then returned to Virginia to care for the estate of his uncle, Peyton Randolph. He was elected to the Virginia convention of 1776 and served on the committee that drew up a bill of rights and a state constitution. The Virginia Assembly elected him attorney general of the state, and between

1779 and 1782 he also served intermittently as a delegate to the Continental Congress.

In 1786 Randolph headed the Virginia delegation to the Annapolis convention and the same year was elected governor of Virginia. He played an important role as a delegate to the 1787 Constitutional Convention (*q.v.*) where he presented the influential "Virginia Plan" and served on the committee on detail that prepared a first draft of the proposed constitution. He did not sign the final draft, however, because he wanted more protection of the rights of states and of individuals. Nevertheless, on his return home he decided to support the document, and in the Virginia convention of 1788 he used his influence to bring about ratification. Charged with inconsistency, he replied that he feared the Union might break up if the Constitution were not ratified.

After President Washington took office in 1789 he appointed Randolph (who had handled much of Washington's personal legal work) to the post of U.S. attorney general. When a feud developed in Washington's cabinet between Jefferson and Hamilton, Randolph tried to be neutral, but this earned him dislike from both sides and brought forth criticism that he was indecisive. Upon Jefferson's resignation as secretary of state in December 1793, Randolph was chosen to replace him. As England and France were then at war and there was strong support in the United States for both antagonists, Randolph's attempt to steer a middle course was difficult. While the Jay Treaty with England was under consideration he performed the delicate task of maintaining friendly relations with France. He also paved the way for the eventual signing (October 1795) of the Treaty of San Lorenzo (or Pinckney Treaty) with Spain, which provided for free navigation of the Mississippi.

Randolph's governmental service was abruptly brought to an end by charges made in an intercepted diplomatic dispatch that he had shown a willingness to accept money from the French in return for influencing the U.S. government against Great Britain. Though the charges were not proved, Randolph resigned from office on Aug. 19, 1795, thus ending a promising political career. He returned to Virginia and resumed his law practice, acting in 1807 as senior counsel for Aaron Burr during his trial for treason. He died on Sept. 12, 1813, at Carter Hall, Millwood, Clarke County, Va.

RANDOLPH, JOHN (1773–1833), a Virginia planter and member of Congress noted for his flamboyant oratorical defense of states' rights, was born at "Cawsons," a plantation in Prince George County, Va., on June 2, 1773. Through his father, John Randolph, and his mother, Frances Bland, he was related to the Randolphs of Turkey Island and the Blands of Westover, two of the most notable families of colonial Virginia; and, through an ancestress, Jane Bolling, he was a descendant of the Indian princess Pocahontas. He received his collegiate education during brief periods of study at Princeton, Columbia, and William and Mary, and read law for a short time under the guidance of a relative, Edmund Randolph, who was attorney general of the United States in Washington's first cabinet.

In 1799 Randolph was elected to the House of Representatives where his rise was so rapid that, after the inauguration of Thomas Jefferson as president in 1801, he was made chairman of the House Committee on Ways and Means and became the leader of the House Republicans. He frequently appeared on the floor of the House in riding habit and flourishing a whip; his debating skill and biting sarcasm made him a feared opponent. After his failure as manager of the impeachment trial of Justice Samuel Chase of the Supreme Court in 1804, and his opposition to Jefferson's effort to acquire Florida, he drifted away from Jefferson and the other Republican leaders. He did not join the Federalists but stood aloof from both parties. About the year 1810 he established his home at "Roanoke," a family plantation, and thereafter added "of Roanoke" to his name to distinguish himself from a distant relative.

Randolph returned to prominence in 1820 when his resolute resistance to the Missouri Compromise made him a powerful figure in the House. After his first election in 1799 he was reelected to the House every two years, except in 1813 when his opposition to the War of 1812 resulted in his defeat and in 1817 when he declined to run. After reelection to the House in 1825, he was elected to the Senate to fill an unexpired term but was defeated for reelection by John Tyler. During these years when party feelings ran high, Randolph's denunciation of Henry Clay's support of John Quincy Adams for the presidency in the disputed election of 1824–25 led him into a duel with Clay in April 1826, but both parties emerged unscathed. Three years later Randolph was a prominent member of the convention that drafted a new constitution for Virginia. In 1830 President Jackson sent him on a special mission to Russia, but ill health forced him to return after only a few weeks at his post. After his return he made a series of speeches denouncing Jackson's proclamation against South Carolina's ordinance of nullification. He died at Philadelphia on May 24, 1833, while waiting for a ship to take him to England.

As a passionate partisan of state sovereignty, Randolph was a forerunner of John C. Calhoun (*q.v.*). He vigorously opposed a national bank, protective tariffs, federal internal improvements (*i.e.*, construction of roads and canals), and interference with the institution of slavery, though he disapproved of slavery and freed his own slaves in his will. He was plagued by ill health throughout his life, and was at times in a state of mental derangement. One of the most brilliant and disinterested, though by no means one of the most useful, of American public men, he was a captivating talker, a delightful letter writer, a scholar, and a devotee of the horse, the dog, and the gun.

RANDOLPH, THOMAS (1523–1590), English diplomat in the reign of Elizabeth I, was the son of Avery Randolph of Badlesmere, Kent. Educated at Christ Church, Oxford, he became principal of Broadgates Hall (now Pembroke college), Oxford, in 1549. Forced to resign in 1553 after the accession of Mary I because of his Protestant beliefs, he went to France, where he may have associated with the Scottish humanist George Buchanan. Shortly after the accession of Elizabeth I (1558) he returned to England and was employed by the queen as a confidential diplomatic agent in Scotland. His letters during this period form an important source for the affairs of the Scottish court. After unsuccessfully opposing the marriage of Mary Stuart and Lord Darnley (1565), he was in 1566 accused by Mary of giving financial support to the rebellion of James Stewart, earl of Moray, and was recalled to England.

Randolph was sent on diplomatic missions to Russia (1568), where he obtained privileges for the English merchants trading there, to France (1573 and 1576), and to Scotland (1570 and 1578). Following the imprisonment of the Scottish regent, James Douglas, 4th earl of Morton, in 1580, Randolph was sent to Scotland by Elizabeth in an attempt to secure his release. He planned to seize the young king James VI and his favourite Esmé Stewart, earl of Lennox, but the plan was discovered; Randolph fled to England and Morton was executed in June 1581. During his last mission to Scotland in 1586, he helped to arrange a treaty between the two countries in which each pledged support for the other in the event of an invasion. From about 1566 he held the chamberlain's office in the exchequer and the office of comptroller of the post horses. Randolph died in London on June 8, 1590.

RANDOLPH, THOMAS (1605–1635), English poet and dramatist whose talent lacked time to mature, was born on June 15, 1605, at Newnham-cum-Badby, Northamptonshire, and educated at Westminster School and Trinity College, Cambridge, where he was elected to a fellowship in 1629. Both at Westminster and Cambridge he earned a high reputation for English and Latin verse, and Ben Jonson adopted him as one of his "sons." Of his three poems to Jonson, one renders thanks for his "adoption," while another answers Jonson's despondent ode on the failure of *The*

New Inn. He died at Blatherwick in March 1635.

Randolph published *Aristippus* and *The Conceited Pedler* (1631), two dramas for performance at Cambridge, *The Jealous Lovers* (1632), a comedy, and verses in various collections. A posthumous collection of his poems (1638) included two other plays, *The Muses Looking-Glass* (performed 1630) and *Amyntas*, a pastoral drama (probably acted 1631). *Hey for Honesty*, a comedy adapted from *The Plutus* of Aristophanes, was published in 1651 with a number of contemporary allusions inserted by the editor. Randolph had a real lyrical gift and some dramatic ability; his early death robbed 17th-century England of an accomplished and genial poet.

The Poetical and Dramatic Works were edited by W. C. Hazlitt, 2 vol. (1875); *The Poems and Amyntas* by J. J. Parry (1917); and *The Poems* by G. Thorn-Drury (1929).

See G. C. Moore Smith, *Thomas Randolph* (1927); S. A. and D. R. Tannenbaum, *Thomas Randolph* (1947). (V. DE S. P.)

RANDOMIZATION, a principle in the theory of experiments designed to avoid the collection of biased and misleading empirical data by ensuring random (or chance) selection and treatment (see STATISTICS, MATHEMATICAL: *Theory of Experiments*).

Experiments are designed to observe the presence or the extent (or both) of the effect of some experimental factor or treatment on some material. In the simplest form of experiment a treated (experimental) quantity (a unit) of material may be compared with an untreated (control) unit. If the material and conditions were exactly homogeneous, then the difference between the two sets of observations would be ascribable to the treatment. Usually, however, the material and conditions are heterogeneous, and the observed difference cannot confidently be ascribed to the treatment, since they may reflect other uncontrolled differences between the experimental and control situations. Thus an investigator's announcement of a finding of some interest is usually followed by similar experiments (replications) performed by different investigators. Also, prior to the announcement, the original investigator is likely to have repeated his experiment to see whether the findings persist with different units of material and at different times.

This degree of control is usual in experimental work and has been customary since about the beginning of the 19th century. For laboratory work in the physical sciences, where homogeneity of material and experimental conditions can be attained to a high degree, such precautions have been broadly adequate. However, by the 1920s, with the growth of experimentation on highly heterogeneous material (e.g., in agriculture, general biology, medicine, meteorology, the social and behavioural sciences), it became apparent that mild and unsystematically applied precautions were not enough. One effort to increase confidence in the generalizability of empirical data was the formulation of the principle of randomization, due to Ronald A. Fisher, which states that before any effect can be said to be ascribable to a given treatment (independent of other known or unknown factors) the experiment must be replicated (i.e., repeated on a number of experimental and control units of material) and that all units of material selected for study must be random samples of the larger population (universe) they are taken to represent. Thus if an experiment is expected to yield a statement about people in general (i.e., the universe of all people) the principle of randomization ideally requires that all people anywhere have an equal opportunity for selection as experimental and control subjects. The word random as used here indicates a basis for sampling from the universe that imitates independent throws of an unbiased coin (see PROBABILITY, MATHEMATICAL). Since most coins are biased (not perfectly symmetrical, for instance), and since the usual methods of tossing them are biased, tables of the so-called random numbers are found in many books on statistics, especially to assist in the random selection and treatment of samples of experimental material.

It must be emphasized that randomization simply reduces the probability of collecting biased or misleading data. On the basis of chance (random) selection from a universe, an atypical sample is merely improbable, not impossible.

As an example of how randomization might be used, consider the case of two surgeons at different hospitals using different methods to remove cancers of a specified type. One finds a higher rate of survival among his patients than does the other, and claims an advantage in his technique. However, the difference may be independent of the differences in surgical technique. It may easily have arisen from a systematic difference between the kinds of patients patronizing the two hospitals. Or, the policy in one hospital may be to perform operations somewhat hastily on early cases of cancer; while patients in the other hospital may be subjected to more prolonged observation. Or, the difference between survival rates may well be due to unsuspected factors; these create the greatest difficulties in experimentation.

All suspected and unsuspected sources of bias should tend to be compensated for a strict application of the principle of randomization. Before randomizing, the experimenters might agree in advance on a well-defined category of patients and on the general circumstances in which the two surgical techniques are to be tested. It may be decided that the sample of patients used in the experiment be limited to those coming for treatment to a particular hospital; or there may be agreement to experiment on patients from all over the country. Also, it may be agreed that all the surgery be performed under strictly predetermined conditions.

One way of randomizing the experiment is to take the units of experimental material (patients under specific circumstances) as they come and to assign them at random to one or the other of the surgeons. As the number of operations so performed is increased, any advantage of one of the techniques should tend to become apparent. Also, any statistically significant difference in the percent of survival of patients can be more confidently ascribed to the difference between the techniques of the two surgeons (including their personal skills) rather than to other factors.

Such a randomization scheme involves considerable practical difficulty. Strict randomization of conditions requires that the patients, their relatives, and hospital personnel be kept ignorant of the identity of the operating surgeon. Such psychological factors become unusually important in the evaluation of drugs, where suggestibility on the part of the patient (see SUGGESTION) may influence response to treatment.

In a so-called double-blind test of the effectiveness of a drug in pill form, an equal number of similar-appearing pills is prepared containing a placebo (a neutral substance, perhaps chalk). Then all the pills are placed in random order and identified by number. The nature of each numbered pill is recorded, but the experimenting physicians and the patients are kept unaware of whether any pill contains the drug or the placebo until the completion of the experiment. Only then are the records of patient response statistically analyzed according to treatment (drug versus placebo). Experiments of this kind have indicated the absence of specific effects of some drugs, and also have shown distinct beneficial effects from placebo.

The general rule is that, unless a treatment is applied to randomly selected units of experimental material, observed effects cannot confidently be ascribed to the treatment.

RANELAGH, formerly a resort by the River Thames in Chelsea, London, Eng. About 1690 land lying east of the Royal Hospital, Chelsea, and bordering the river was acquired by Richard, Viscount Ranelagh, later earl of Ranelagh. He built a mansion and laid out gardens, which in 1742 were thrown open as a proprietary place of entertainment. The Rotunda was erected for concerts and the gardens became a resort of fashionable society. By the close of the 18th century Ranelagh was ceasing to attract visitors, and in 1803 the Rotunda was closed. Ranelagh House and the Rotunda were pulled down in 1805, and in 1826 the site of the gardens was bought for the Royal Hospital.

RANGE (IN AGRICULTURE) refers to extensive areas of more or less "natural" grasslands. The vegetation of ranges may include tall grass prairies, steppe, desert shrub, savanna, woodland, chaparral, tundra or forest, the only criterion being that there be enough grass in the vegetation to be profitably grazed. The true tall grass prairies such as those of the North American midwest, the Ukraine, parts of Hungary and Argentina are usually too well suited to cultivated crops to be left in range. Ranges are more generally confined to areas of marginal or sub-marginal farming or to areas entirely unsuited to cultivation.

Range Formation.—The naturalness of range vegetation is a matter of degree. In much of the coast and foothill ranges of California the original, largely perennial grassland has been almost completely replaced by an introduced annual Mediterranean flora. These areas are called annual range perhaps because the replacement of one vegetation by another was not intentional even though brought about by the activities of man and his livestock. Extensive areas of forest have been converted to grassland by fire or cutting or both. In other areas, selective cutting and good forest management have opened up stands of timber permitting an increase of grass for grazing purposes. Good forest management and good range management are often complementary rather than competitive. Few, if any, ranges are totally uninfluenced by man or his livestock. They are natural only in the sense that they are not artificially established by cultural means.

Fire is a natural feature of grassland vegetation, whether set by man or other agencies. The elimination of fire may be considered a disturbance which in desert shrub, savanna or woodland vegetation frequently invites the dominance of trees and shrubs to the near exclusion of the grass. Fires that tend to favour the continuance of grassland are prevented primarily by heavy grazing which removes most of the combustible material. They are also reduced in frequency by precautions against the setting of fires.

The use of fire as a management practice is common in many parts of the world, but is frequently ineffective in the control of woody vegetation because of heavy grazing. Satisfactory burns usually require deferment for a growing season to accumulate combustible material, and the value of the unused grass must be weighed against the expected value from brush control.

Management Practices.—Some of the most important range management practices are given below. (1) Proper stocking. An adequate surplus of grass must always be left at the end of the grazing season to protect the soil and to supply food reserves for the next season's growth. (2) Uniform grazing. Livestock graze more closely near water, salt, feeding areas, fence corners and other places where animals concentrate. They graze the steep parts of the range much less than the flats. Some corrective measures are: cross fencing into smaller pastures, placing salt in little used parts of the range, developing more watering and salting places, herding with greater care, etc. (3) Deferment. Ranges may be deferred early in the season to protect the grass during a period when it is using up food reserves; they may be deferred late in the season to allow the grass to recover from grazing and store food reserves; they may be deferred for an entire season for burning or to permit seed production in order to improve the vigour and density of the stand. (4) Control of undesirable plants. This may be accomplished by manipulation of livestock to either graze hard or rest at critical times or by selective herbicides, fire or mechanical treatments such as mowing, beating, root plowing, etc. (5) Encouragement of desirable plants. This is usually done by livestock manipulation or burning, but in special cases overseeding and/or fertilizing result in substantial improvements. (6) Proper seasonal use. High mountain ranges can be used only in summer, annual ranges are most productive in spring and many desert ranges are best used in winter. In order to use many ranges at the proper time, livestock must often be trailed or trucked considerable distances. (7) Pest and game control. In order to obtain maximum yields, animals that compete with livestock for forage must be controlled as well as parasites that attack livestock.

Overgrazing.—The most pernicious and chronic problem in the management of ranges is overgrazing. Too heavy use of the

vegetation reduces production of forage, exposes the soil to sealing, baking and erosion, reduces the infiltration of water and the effectiveness of precipitation, increases runoff and flood hazards and induces changes in the botanical composition of the vegetation. These changes invariably involve an increase in unpalatable, woody, thorny or poisonous plants and a decrease in the more palatable and desirable species.

Overstocking and the fire control that goes with it have resulted in an alarming increase in woody vegetation in the savanna, woodland, chaparral and desert shrub areas of the world. Overstocking has practically denuded vast areas of rangeland in nearly every continent and the degeneration of range condition is one of the most serious problems in agriculture.

Stockmen and technicians alike have consistently overestimated the capacity of ranges to produce. One must become resigned to low yields per acre, and ranges can be profitably used only because the forage is cheap. As soon as elaborate management practices are required as correctives for bad management, the range forage is no longer cheap and its use often becomes unprofitable.

(J. R. HN.)

RANGE FINDERS, instruments used to establish surveys and maps, to direct gun, rocket, and missile fire, to test and study air vehicle characteristics, and to determine the lens focus setting for cameras. Triangulation methods have long been used for the determination of ranges, and precise optical methods have been devised for this purpose, but with the development of pulse-time techniques for use with radio equipment and the development of lasers (*q.v.*) a new series of instruments evolved for the determination of range. (See RADAR.) The development of radio ranging at the beginning of World War II became an important factor in naval gunnery and anti-aircraft fire; large optical range finders formerly indispensable in the direction of such fire assumed a secondary or stand-by role. Optical range finders have the advantages of high resolution, compact size, relatively simple maintenance, and accuracy at short ranges; but they are unreliable at long ranges and during periods of bad visibility, require a relatively long time to make the range determination, and, for most purposes, are useless at night.

Basically, an optical range finder is a triangulation device with which two angles and the included base are measured to determine the range to the target situated at the apex of the triangle so formed. The most accurate ranging is accomplished by: (1) a two-station system of triangulation in which the base line is long and the optical stations are separated by distances of several hundred yards or many miles; (2) the short base monostatic range finder, a one-station system of triangulation which is a self-contained optical system; its accuracy depends on the precise mounting of its optics on an optical bar.

The two-station system suffers from several difficulties: establishing time coincidence when measuring ranges to moving or intermittent targets; maintaining a complex communication network to coordinate the ranging; insuring that the two stations are set on a common target; and calculating the range by trigonometric computations. The one-station system, at the expense of accuracy, avoids these difficulties.

Two-Station System.—The two-station system of triangulation has undergone a high degree of development throughout recorded history beginning, perhaps, with the attempts of the Egyptians who were required to reestablish property lines after the annual Nile River floods. In modern times, the development of the optical theodolite resulted in highly precise measurements. The theodolite is used to measure angles—measurements which, in order to minimize operators' errors, are averaged from a number of readings. By United States Coast and Geodetic procedure an angle is turned 16 times in a first order survey, 4 times in a second, and twice in a third. The accuracy of the distances so measured must not have an error exceeding 1 in 25,000 in a first order survey, 1 in 10,000 in a second, and 1 in 5,000 in a third. This precision is possible only because the targets are fixed and easily identifiable from each other.

In many situations, especially in military usage, the targets are either moving or intermittent, as in the determination of the

ranges to vehicles or gun flashes. In such cases, a reading can be taken only once and the two base angle readings must be taken simultaneously. An elaborate communication network between the stations must be set up and timing coincidence must be established. One military system consists of a shutter assembly which is attached to the objective of a sighting telescope. A network of these instruments is established by survey with the shutters connected over communication wires so that the shutters can be simultaneously opened or closed electrically from a central control station. This system is particularly useful in spotting muzzle flashes from artillery fire. When an observer notes a muzzle flash through his telescope he closes the shutters, thus establishing time coincidence. The operators then take a reading of the bearing of their sighting telescope and relay the bearing position to the central control station where a range plot is made.

For proof-testing, checking the accuracy of anti-aircraft fire, and observing the flight of rockets a more elaborate network is established by using phototheodolites. A phototheodolite, as shown in fig. 1, consists of a camera with a long focal length lens

BY COURTESY OF U.S. ARMY SIGNAL CORPS

FIG. 1.—PHOTOTHEODOLITE

mounted on a theodolite base. The theodolite is turned by a handwheel or synchronous motor directed by an operator, who sights through a telescope fixed to the theodolite base. Time coincidence among the phototheodolite stations is established by a signal transmitted over a communication system. Time markers are actuated to give an indication printed on the film; the signal may also operate the shutter. It is possible to operate the phototheodolites over base lines as long as 15 mi. The camera, usually a 35-mm. movie type, takes a picture of the target being tracked by the operator and prints fiducial marks, or reference points, which establish the zero position on the film, as well as pictures indicating the position of the theodolite base in both azimuth and elevation.

The angular errors in tracking are reduced by developing the film and making corrections to the indicated azimuth and elevation readings by applying tracking corrections determined from the measured position of the target with respect to the fiducial marks. By averaging measurements made by a system of four or five phototheodolites, it is possible to obtain range accuracies of 1 in 10,000 at ranges less than 10,000 yd.

Short Base Range Finders.—Attempts were made as early as 1770 to couple two theodolites closely on a short base line to circumvent communication difficulties in military range finding. Georg Friedrich Brander in 1781 built a range finder for one operator and Alexander James Adie (1860) constructed a split coincidence range finder. Archibald Barr and William Stroud in England culminated a rapid development of range finders in 1888 when they brought out their coincidence range finder, a prototype of modern instruments. Later, in 1893 the Carl Zeiss firm in Germany built a stereoscopic range finder. The Germans continued to favour the stereoscopic type made by both Zeiss and Carl Goertz; the British favoured coincidence types. U.S. manufacturers,

Bausch and Lomb, Eastman Kodak, and Keuffel and Esser, continued to make both types. Prior to and during World War II, developments in military range finders were concerned largely with refinements of these two designs.

In the years following World War II, military developments begun during the war culminated in the perfection of both coincidence and stereoscopic range finders in tanks. In most instances, the range finder was coupled to the tank cannon so that aiming and ranging pointed the cannon automatically in the proper direction and at the proper elevation for the target range and projectile in use. (See *Tank Range Finders* below.)

Coincidence and Stereoscopic Range Finders.—In the development of the modern range finder there was considerable controversy concerning the comparative effectiveness of the coincidence and stereoscopic range finders. The two appear similar except that usually the coincidence type has a single eyepiece and the stereoscopic type has two eyepieces. Fig. 3 and 5 illustrate the schematic arrangement of the commonly used coincidence and stereoscopic range finders. Monostatic range finders are built, self-contained, with two optical extended "arms" which define the base length. The outer case usually contains windows, the optical square and the eyepieces. An inner "optical bar," insulated from temperature differentials and vibrations, contains the objectives, deviation prism, and the reticles. As the field of view is small, the range finder is mounted on bearings and must be rotated to follow the target. The range operator who observes the images formed by the two objectives adjusts the range drum to establish coincidence or stereoscopic contact; the range can then be read from the drum. Monostatic range finders having a base length of one yard or less are portable and used by armies in the field; they are accurate to 1,000 yd. Larger range finders having base lengths of 4½ to 40 ft. were used to measure ranges up to 20 mi. to adjust naval and anti-aircraft fire and are used in tanks.

Accuracy of Monostatic Range Finders.—The fundamental equation for the range finder can be derived from fig. 2. B is the base length of the range finder, O_1 is a right angle and θ is the convergence angle to the target from O_2 . The convergence angle is very small, hence: $R = B/\theta$ (approximate) if the angle θ is expressed in radians. The error in a range reading arises from the error in measuring the convergence angle. The equation for the range error may be derived from fig. 2: $dR = d\theta R^2/B$. As indicated by this formula, the range error varies as the square of the distance to the target.

In measuring the accuracy of range finders the term "unit of error" (UOE) is frequently used. It may be defined as the minimum angle which can be detected by an operator under ideal

FIG. 2.—GEOMETRICAL CONSTRUCTION OF EQUATION FOR DETERMINING RANGE ERROR, dR , OF RANGE FINDER (see TEXT)

conditions and is equal to approximately 12 seconds of arc (0.00006 radians). Considering only this visual acuity of the observer and the optical magnification of the range finder, the error in the convergence angle is: $d\theta = (\text{UOE})/M$. The idealized error in optical range finders therefore is given by the formula: $dR = (\text{UOE}) R^2/BM$. If the range is given in thousands of yards, the base length in yards, and the UOE accepted as 12 seconds of arc, then the theoretical range error in yards for one UOE is: $dR = 60R^2/BM$.

In actual field use an operator cannot sense an error as small as 1 UOE because of limitations in the optical quality of the instrument, irregular shape of the target, and atmospheric haze and shimmer. Additional error in measuring the convergence angle arises from temperature instability of the instrument or improper adjustment. A range finder which yields maximum errors 4 times

those indicated by the above formula would be considered an excellent instrument.

The accuracy of optical range finders diminishes as the distance between observer and target increases; theoretically the range error varies as the square of the distance. In this respect optical instruments differ from radar and laser range finders, which determine distance by measuring the time required for radio or light waves to travel from the range finder to the target and back again. Because the speed of radio or light waves is substantially constant, the range error is largely independent of distance.

Construction.—The two ends of the base line are defined by the optical square which changes the incoming light path at the two arms of the range finder by 90° . A penta prism P, as shown in fig. 3, is ideally suited for the purpose since it has the character-

FIG. 3.—COINCIDENCE RANGE FINDER

istic of changing the light path through a constant fixed angle independently of the incident angle. The prism has its two reflecting surfaces 45° to each other. In larger range finders it is necessary to use mirror surfaces M as reflecting surfaces, as shown in fig. 5, for it is impossible to obtain satisfactory prisms in the larger sizes. The choice of penta prisms or mirrors depends on the size of range finders and not on the type.

In order to effect coincidence or establish stereoscopic contact it is necessary to displace the image which is formed through one arm of the range finder. This can be accomplished by movement of one of several optical components. To accomplish the displacement in military instruments it proved most suitable to use a sliding lens compensator or deviation prisms; two types of deviation prisms were found most useful. One type consists of a low power prism placed in the converging light from the lens O_2 in one arm of the range finder, fig. 3. As the prism is moved toward the lens (i.e., from D_1 to D) it causes a greater displacement of the image formed by that arm. A calibrated scale coupled to the

FIG. 4.—FIELD OF COINCIDENCE RANGE FINDER

prism indicates the range when this image is adjusted to coincide with the image from the other arm. The second type of deviation prism device, known as a diasporameter, consists of two low power prisms placed in the parallel beam ahead of one objective lens. When the bases of the prisms are vertical and opposed, the deviation caused by one prism is cancelled by the deviation from the other. If the prisms are rotated in opposite directions about the optical axis, the vertical displacements still will cancel, but the horizontal displacements introduced by the rotation will add. The result will be a horizontal displacement of the image.

The sliding lens compensator consists of two low power lenses, one convex and one concave, placed in the parallel beam ahead of one objective lens, as indicated in D, fig. 5. When both lenses are centred on the optical axis of the range finder, no deviation is introduced. If one lens is moved horizontally, a corresponding deviation of the image will result, because the off-axis section of the lens then in use introduces a convergence of light rays toward the displaced axis of this lens.

The range finder includes a telescope not only for the purpose of forming an image from the radiation arriving at the penta prisms but also to aid the operator in seeing objects at a distance. The difference in the two types of range finders is apparent in the telescopic system. The two objectives of the coincidence range finder form an image in a common focal plane which may be viewed by either a single or a binocular eyepiece. In a stereoscopic range finder two complete telescopes are used with their own objectives and eyepieces. Stereoscopic contact is established physiologically by the operator.

The presentation in a coincidence range finder is achieved by

BY COURTESY OF U.S. ARMY ORDNANCE CORPS

FIG. 5.—STEREOSCOPIC RANGE FINDER WITH AUTOCOLLIMATOR

melding the images from the two arms. In simpler types of range finders half-silvered mirrors may be used; in more precise instruments the prism combination becomes complex to achieve the proper presentation. In fig. 3 the prism is only indicated; actually it is made up of a combination of roof prisms. The prism combination may be so constructed that not only the fields from the two arms are shown but also, as indicated in fig. 4, a scale indication of the range is made. As shown in fig. 4, the target may be presented as a split image with the field divided in the centre. Adjustment of the range drum shifts one field until coincidence is established as shown by the dotted line in the figure. Other presentations might be used: as a superimposed image as shown in fig. 7 or as a double image with one inverted. The split image adjustment is particularly effective when definite vertical lines are visible on the target. In using the split image the fineness of the dividing line is important; for precise instruments, a satisfactory line can only be produced by coincidence prisms. In order to insure the optimum performance an adjustment to correct the relative location of the two target images must be provided so that upon adjustment the images match in the field. This is done with a "halving adjustment." The adjustment may be effected by rotating a parallel plate in the converging beam of one of the arms.

The two telescopes of a stereoscopic range finder have reticles with a single mark or a "picket" of spaced marks, known as the wandemark. The marks are so placed that when they are viewed by the two eyes of the observer the marks are fused and appear to float in space because of the stereoscopic perception of the observer. If the images of the targets are positioned on the reticles with the proper spacing, the target will be seen stereoscopically in three dimensions. By means of the deviation prisms the image may be displaced and stereoscopic contact is established when the

FIG. 6.—FIELD OF STEREOSCOPIC RANGE FINDER

target appears to be at the same position in depth as the reticle spot. Under adverse lighting conditions it is advantageous to illuminate the wandmark so that a spot of light appears in the field. If the picket of wandmarks as shown in fig. 6 is used, the spacing of pickets on each reticle is such as to form a series of lines which in the field of view apparently recede into space.

As the range finder is a precise optical instrument, it is subject not only to the shifting of its parts because of temperature changes, vibration, and shock, but is also subject to the idiosyncrasies of the operator. For these reasons it must be calibrated often in use and when operators are changed. The most effective adjustment is to range on an object at infinity such as the moon or stars. Lacking these a "lath" is used for small range finders which consists of a rod having two marks spaced in accordance with the dimensions of the optical separation of the instrument. These marks when viewed through the range finder have the appearance of being at infinity.

Large stereoscopic range finders often contain a built-in autocollimator to eliminate the need for frequent calibration. The autocollimator, shown in fig. 5, consists of two identical lenses A, which are engraved with marks and illuminated through small prisms. The mark on lens A₂ is at the focus of lens A₁ and is projected by the Porro reflector M₃ to the objective O₂ and thus to the operator's right eye. The mark on lens A₁ is similarly projected to the operator's left eye. The marks appear as an object at fixed depth, because each lens is a target for the other; an accidental shift of one lens produces equal shifts in both images

FIG. 7.—PHOTOGRAPHIC RANGE FINDER COUPLED TO CAMERA

and no change in the apparent depth of the mark. Range measurements are made by manipulating the deviation device until the image of a target is brought to the same apparent depth as the mark. Thus, range measurements are unaffected by misalignment of any optical element in the instrument, because the light rays from the target and the reference marks are combined, and any shifting of parts in the two telescopes has equal effects on the images of the target and the mark.

Height Finders.—When ranging on air targets, the range finder determines the slant range. Often the altitude or vertical component to the target is required. This, a function of the elevation angle and the slant range, may be computed mechanically by a system of cams.

Photographic Range Finders.—With the development of press photography and the interest in the candid camera, rapid adjustment of the camera focus became important. A range finder made by the Kalart Company, permitting the rapid and accurate focusing of the lens, is shown in fig. 7. Photographic range finders are invariably of the coincidence type and may be of either the split image or superposition of image type. They may be coupled directly to the camera through a mechanical linkage or they may be separate and give a range scale reading. An attachment is also available that projects a spot of light which, under unfavourable lighting conditions, forms a target reflected from the subject which can easily be brought into coincidence in the range finder. A number of range finders made by various camera manufacturers have appeared on the market. These, although simple in construction, may have various complexities. (See *Coincidence and Stereoscopic Range Finders* above.)

Eastman Kodak Company marketed split image coincidence finders, one type with a split image coincidence prism was adjusted

BY COURTESY OF U.S. ARMY ORDNANCE CORPS

FIG. 8.—STEREOSCOPIC TANK RANGE FINDER

by moving one objective. Zeiss made a range finder having an adjustment by a diasporameter. The Leica range finder is similar to that shown in fig. 7.

Camera range finders have base lines which may be an inch and a half long to about four inches. That the instrument must be carefully made can be understood, as a movement of 3° in the mirror corresponds to a change in the setting of the range finder from three and one-half feet to infinity.

Tank Range Finders.—Range finders for use in tanks were developed in Germany and the United States during World War II to increase the accuracy of gun fire at long range. The stereoscopic range finder was used to avoid the double or split image required in coincidence instruments, and thus permit clear observation of the target during firing.

One U.S. instrument, which was produced in quantity starting in 1948, had a 60-in. base length and seven-power magnification. A later model with a 79-in. base length and 10-power magnification (shown in fig. 8) also was produced. This range finder was accurate within 40 yd. at 2,000 yd., which is equivalent to a vertical error on the target of only 15 in., for typical tank ammunition.

Special tank turret shapes are required to house and protect the range finder, and the instrument must be carefully designed and mounted to withstand the shocks encountered by tanks in combat. To retain accuracy and to eliminate the need for frequent calibration, tank range finders contain autocollimators, as shown in fig. 5.

A ballistic computer is used in conjunction with the range finder to reduce the time required to fire the tank gun and to utilize the accuracy of the range finder effectively. The range setting of the deviation device is converted by the computer into the angle at which the gun must be aimed above the target to compensate for the effect of gravity on the shell. If the range finder is used as the gun sight, the computer is built into the range finder, and points the gun at the required angle above the target when the range finder is aimed at the target. If a separate instrument, such as a periscope, is used to aim the gun, the computer is a separate instrument, and is connected either electrically or mechanically to the range finder and the periscope; however, its function and purpose are the same.

Stadiometric Ranging.—The determination of distances by stadia rods has long been used in survey work. The method depends upon solving the triangle established by the angle subtended at the observer's position by an object of known size to determine the range to the object. In surveying procedure a stadia rod having markings with known spacings is observed through a theodolite and standard tables give the range to the rod. A range finder using similar principles is used for military purposes. It consists of a telescope or binoculars having either a lattice of horizontal markings, or a single mark or pattern of adjustable size. By observing the image of a man, or a vehicle of known size, superimposed on the reticle, the angle subtended by the object is determined. Inasmuch as aircraft have well-known dimensions, the stadiometric device is used to determine ranges to aircraft.

RANGER, in U.S. military usage, a soldier specially trained to act in small groups which make rapid surprise raids on enemy territory; the British term for such units is commando (*q.v.*). In the United States ranger has also been the designation for the Texas state constabulary and for national park supervisors and forest wardens.

Ranger units originated during the French and Indian War (1754–63), when the British formed special units of expert woodsmen and marksmen to range the forests on scouting, screening, and harassing missions. Notable among these was Rogers' Rangers, a battalion commanded by Maj. Robert Rogers.

During the American Revolution, both British and American forces employed rangers. At that time infantry tactics were based on the volley fire of close-ranked infantry of the line. Each regiment also contained a light infantry company, often armed with rifles rather than the muskets of line companies, for employment in advance of the main force or on its flank. These companies were sometimes detached from their parent units and grouped to fight as a body. This led to the formation of entire regiments of light infantry, sometimes referred to as rifle corps or rangers. Among American units of this type were Daniel Morgan's Virginia Rangers and Thomas Knowlton's Connecticut Rangers. Similar British forces were recruited from loyalists, notably Maj. John Butler's battalion (Butler's Rangers), formed to operate in conjunction with Indians, and the Queen's Rangers.

The term "ranger" recurred in U.S. military usage when on Jan. 12, 1812, Congress authorized enlistment of six companies of these troops for service on the frontier. The *Army Register* of May 1, 1813, listed 12 companies of rangers among the units of the Army. In 1832, the force authorized for the Black Hawk War included 600 mounted rangers. This first suggestion of combining the functions of rangers and cavalry was an outgrowth of changed tactical needs; the tide of settlement having moved beyond the eastern forests, military operations were now in more open terrain, where mounted forces had superior mobility.

The concept of ranger-cavalry was reinforced by the experience of the Republic of Texas, which recruited mounted ranger companies to protect its outlying areas against Indians and Mexicans. During the Mexican War companies of Texas Rangers were formed into regiments and mustered into federal service. They operated both as conventional cavalry and as rangers, on scouting, patrol-

ling, and raiding duty. Their detached duty, independent attitude, and distinctive appearance probably provided an initial basis for the association of the term "ranger" with irregular, paramilitary forces.

During the Civil War, both Union and Confederate organizations adopted "ranger" as part of their unit designations without reference to their actual military character and employment. However, true ranger units played a significant part in Confederate operations. Partly because of the type of service it performed and partly, no doubt, because of its state origin, the 8th Texas Cavalry was known as Terry's Texas Rangers. The concept of rangers as irregular forces was given impetus when the Confederate Congress passed the Partisan Ranger Act in 1862. Partisan rangers were entitled to reimbursement for equipment that they captured—an attempt to apply the law of maritime prize to land warfare. The best-known leader and foremost exponent of ranger operations in the Civil War was a Confederate, Col. John S. Mosby (*q.v.*).

Ranger units reappeared in U.S. military organization in World War II, when six ranger battalions were formed, five serving in the European-African-Middle Eastern theatre and one in the Pacific theatre. Composed of specially trained and conditioned men, these units made sudden, hard-hitting raids behind enemy lines, carrying out demolition and intelligence missions. The lessons of this experience led to the formation in 1950 of the air-borne ranger infantry company as an integral part of each U.S. infantry division. Six such companies were eventually employed in the Korean War. In 1951, however, it was decided that concentration of these trained men in special units was less desirable than spreading them through conventional units, where a larger number of soldiers would have the benefit of learning the combat techniques in which the rangers were especially skilled. Thereafter the U.S. Army continued to conduct special ranger-training for individuals but maintained no ranger units.

The Texas Rangers, after their federal service in the Mexican War, served as a state constabulary organized along military lines, maintaining law and order against Indians, bandits, and other lawless elements. As local government became more effective the need for such a force declined. In 1901 it was reorganized as a state law-enforcement agency. In 1935 the Texas Rangers were merged with the state highway patrol under the Department of Public Safety.

In the National Park Service, the U.S. Department of the Interior established in 1916 a force of national park rangers, whose functions include protection and conservation of forests and wildlife in the national parks, enforcement of park regulations (for which they have police power), and assistance to visitors.

Similar functions with respect to the national forests were assigned to the rangers of the Forest Service, established in 1905 as an agency of the U.S. Department of Agriculture. Forest rangers are particularly noted for their activities in the prevention and fighting of forest fires.

RANGOON (Burmese YANGON), the capital of the Union of Burma, lies on the left bank of the Rangoon or Hlaing River, 21 mi. (34 km.) from the sea. Municipal area 77 sq.mi. (199 sq.km.). Pop. (1962 est.) 800,993. The central part of the city (planned in 1852) is laid out on a system of blocks, each 800 by 860 ft. (244 by 262 m.), intersected regularly by streets running north-south and east-west. The block system was applied also to the principal suburb, Kemmendine, on the west, but other suburban areas developed to the north mainly after 1918 have a less rigid layout. Of the many fine public buildings notable are the port commission offices, the customs house, the Mayo Marine Club, and the modern law courts. Other buildings include the general hospital, the Anglican and Roman Catholic cathedrals, and the city hall on Sule Pagoda Road, which leads northward through the town centre and contains the charming Sule Pagoda. Nearby is Independence Memorial. The many places of worship include Buddhist pagodas and monasteries, and mosques, temples, and

JULES BUCHER—PHOTO RESEARCHERS, INC.

DEVOUT BURMESE CITIZENS PERFORM AN ACT OF MERIT BY SWEEPING THE TILE FLOORS OF SHWE DAGON PAGODA, THE NATION'S MOST IMPORTANT BUDDHIST SHRINE

churches for Muslims, Hindus, Parsees, and Christian denominations. The Royal Lakes (Kandawgyi; water area 160 ac. [65 ha.]) to the northeast are surrounded by a wooded park, and nearby are the spacious zoological and botanical gardens.

The most notable institution in Rangoon is the Shwe Dagon Pagoda, a great golden stupa which dominates the city from the north and forms the focus of Burmese religious life. Rising to a height of 368 ft. (112 m.) it stands on an eminence 168 ft. (51 m.) above the level of the city. It is built of brick, in the form of a cone raised over a relic chamber which by tradition contains eight of the Buddha's hairs. The building is covered with pure gold from base to summit, and once in every generation the gold is renewed by public subscription. The Shwe Dagon Pagoda is a place of pilgrimage at the great Buddhist festivals, when people come from all parts of Burma to meditate there; the place of worship is the surrounding terrace, 900 ft. by 685 ft. (274 by 209 m.). In 1950-52 the great Kaba Aye Pagoda and the nearby artificial cave with assembly hall (1953-54), dedicated to world peace, were built a few miles farther north. There are several hotels and clubs. At Mingaladon, about 11 mi. (18 km.) N, is one of the finest 18-hole golf courses in Asia.

The University of Rangoon, constituted in 1920 on the collegiate principle, was reconstituted in 1948 on a unitary basis; it formerly included the University College, Judson (American Baptist Mission) College, the medical college, and the teachers' training college. Affiliated institutions in Mandalay were formed into a separate university in 1958. In 1963 the technological departments in Rangoon were also formed into a new university. Most of the university buildings in Rangoon were erected between 1927 and 1930 on a site overlooking Victoria Lake, 5 mi. (8 km.) N of the town, but extensive additions, mainly in the technological branches, were erected in the 1950s, also on the north side of the city.

Rangoon contains the principal business houses and banks of Burma, and is also an industrial centre. Rice milling (at Dala to the south), oil refining (at Syriam to the east), and teak working, which form the staple industries, are carried on outside the town proper; but after World War II, and mainly from 1958, there

was a considerable expansion of light industry, with more than 500 factories, mostly small. The chief exports are rice, bran, timber, oil cakes, pulses, lead, zinc ore, cotton, oilseed, and tobacco.

Rangoon is the principal seaport of Burma, handling more than 80% of the total trade and about 1,000 vessels annually. Its busiest season is from late December to mid-May, when rice is exported. The city is also the centre of rail and river communications for the whole of Burma. Internal transport is effected principally by bus, the former electric streetcar line not having been revived after the Japanese occupation in World War II. The international airport is at Mingaladon.

History.—Though the Shwe Dagon Pagoda is a shrine of great antiquity and has been a place of pilgrimage for many centuries, Rangoon as a town is modern. The place was of no commercial or other secular importance until in 1755 King Alaungpaya (the founder of the last dynasty of Burmese kings) conquered it and developed it as a port and commercial centre to replace the old port of Syriam which had been a focus of resistance to his authority. He gave it the name of Yan Kon ("the end of strife"), usually transliterated into English as Rangoon. Alaungpaya laid out the town along the river bank, but it occupied only a fraction of its present area. In 1824 Rangoon was taken by the British on the outbreak of the First Anglo-Burmese War, but was restored in 1826. It was captured a second time in 1852 and with the rest of the province of Pegu was placed under the East India Company. After 1852 the modern street plan was adopted. Most of the area lay below high-tide level and much effort was devoted to raising the land so as to prevent the usual flooding. In 1892 the sewage system was introduced and Rangoon developed a good drainage system. The water supply, drawn at first from the Victoria Lake, was later drawn from a large reservoir lake at Hlawga, 17 mi. (27 km.) N, and from the Pegu Yoma water project completed in 1941.

As the town developed, it became largely an Indian city. Most of the labour in the port and the town was immigrant Indian labour, though much of the skilled labour, especially in building trades, was Chinese; the trading and clerical communities were also mainly Indian. Rangoon was thus by no means a typical Burmese city; in 1931 out of a population of 400,415, there were only 121,998 Burmese, the rest being Hindus, Muslims, Chinese, Europeans, and Anglo-Burmans. As a result of the Japanese invasion of Burma in 1941-42 the Indian and European population was much reduced, and the independence of Burma in 1948 caused a second exodus of many who had returned after the war. Rangoon thus became much more a Burmese city. The disturbed condition of the country after 1948 led to an influx of refugees from villages: by 1958 it was estimated that of the total population, 600,000 were Burmese, and of these one-third were refugees living in insanitary temporary quarters which they had erected along the road sides. In December 1958 the city was brought under military administration and energetic measures were taken to remove the squatters to the newly built satellite settlements of Okkalapa and Thabeta on the eastern margins of the city.

(B. R. P.)

RANGPUR, a municipal town and district in the Rajshahi division of East Pakistan. The town, headquarters of the district, lies on the Little Ghaghat River 100 mi. NW of Mymensingh. Pop. (1961) 40,634. It is a long, straggling town, with a railway station at one end and the public offices three miles (five kilometres) away at the other. Roads radiate in all directions. The town has a college affiliated with Rajshahi University, technical, agricultural, and primary teacher-training institutes, two public parks, and two main libraries. Besides the industries of weaving and *bidi* (local cigarette) and cigar making, the town is noted for the manufacture of durries (cotton carpets).

RANGPUR DISTRICT, with an area of 3,704 sq.mi. (9,593 sq.km.) and a population (1961) of 3,796,043, is one vast plain. The greater part, particularly toward the east, is inundated during the rains, and the remainder traversed by a network of streams. The river system is constituted by the Brahmaputra and its tributaries, chief of which are the Tista, Dharla, Sankosh, and Dudhkumar. About three-fourths of the district is under continuous cultivation.

Staple crops are rice, oilseeds, jute, and tobacco, and chief occupations fishing, paddy husking, and the making of baskets and fishing nets. The district is well served by the Pakistan Eastern Railway. Saidpur, 22 mi. (35 km.) W of Rangpur town, has railway workshops. (K. S. Ad.)

RANJIT SINGH, MAHARAJA (1780–1839), Indian ruler and leader of the Sikhs, known as the "lion of the Punjab," was born at Budrukhan on Nov. 13, 1780, or, according to another version, at Gujranwala on Nov. 2, 1780; he was the son of Sirdar Maha Singh, whom he succeeded in 1792 as head of the Sukarchakia branch (*misl*) of the Sikh confederacy. By birth the head of one of several competing Sikh groups, he rose to primacy through his own genius, and was one of the ablest Indians of the century.

In 1799 Ranjit Singh took possession of Lahore. In 1801 he defeated the most powerful Sikh *misl*, the Bhangis, and in 1802 seized Amritsar, the second of the twin Sikh capitals. He was then indisputably the leading Sikh chief and set out to enlarge his dominions. On Jan. 1, 1806, he agreed to exclude Holkar (*q.v.*) from his territory, and in that year he took Ludhiana; but this brought him into conflict with the British, who claimed the land up to the Sutlej. The matter was settled by Charles Metcalfe's mission (1808) which led to the Treaty of Amritsar (April 25, 1809). Ranjit decided not to cross swords with the British and to expand instead to the north and west. From this time dates the formation of the famous Western-trained Sikh army, with its formidable artillery and numerous expatriate European officers. In 1818–19 he took Multan and Kashmir. By 1820 he had consolidated his power in the whole Punjab between the Sutlej and the Indus. He added Ladakh and Peshawar to his kingdom in 1834 and repulsed an Afghan counterattack on Peshawar in 1837. In 1838 he agreed to the tripartite treaty with Lord Auckland and Shah Shuja for the restoration of the latter to the Afghan throne.

Ranjit Singh freely employed Hindus and Muslims as well as Europeans, but always on a basis of Sikh supremacy. Little was done to promote irrigation or trade, the revenues being consumed by the needs of the army. He died at Lahore, on June 27, 1839, and in little more than six years the state collapsed through the internecine strife of rival chiefs.

See Khushwant Singh, *Ranjit Singh* (1962); J. D. Cunningham, *A History of the Sikhs* (1849; rev. ed. 1919). (T. G. P. S.)

RANJITSINHJI, KUMAR SHRI (1872–1933), maharaja of Nawanagar, who first made his name as a great cricketer and then as an enlightened ruler. Of ancient Rajput stock, he was born on Sept. 10, 1872, in Sarodar, Kathiawar, in India, and completed his education at Trinity College, Cambridge. He played cricket for Sussex, which county he captained during 1899–1903; he played for England v. Australia 15 times, scoring 985 runs. In 1899 he amassed over 3,000 runs in one season. Wherever and whenever he batted, he evoked an atmosphere of magic by the effortless grace and speed with which he scored his runs.

He succeeded as maharaja in 1906 and became a progressive ruler and statesman. After serving in France in World War I, he represented the Indian states at the League of Nations assembly in 1920 and in 1930 attended the first Round Table Conference to consider the constitution of India. He died at Jamnagar, Nawanagar, on April 2, 1933.

See R. Wild, *The Biography of Colonel His Highness Shri Sir Ranjitsinhji* (1934). (N. Cs.)

RANK, OTTO (1884–1939), Austrian psychologist, was one of the earliest and most influential adherents of the psychoanalytic school. He was born in Vienna on April 22, 1884, and took his doctorate in *Germanistik* at the University of Vienna in 1912. While most of Freud's other disciples devoted themselves primarily to clinical applications, Rank applied his principles to the study of mythology, literature, and art. His first important work was *Der Künstler* (1907; later expanded and rewritten under the title of *Art and Artist*, Eng. trans. by C. F. Atkinson, 1932); it invoked the Freudian theory of dream mechanisms to explain the mental processes of the artist. His two best-known publications, *Der Mythos von der Geburt des Helden* (1909; Eng. trans., *The Myth of the Birth of the Hero*, 1952) and *Das Inzest-Motiv in Dichtung und Sage* ("The Incest-Motive in Poetry and Legend,"

1912), attempted to show how the so-called Oedipus complex supplied an abundance of themes and motives for poetry and myth.

Rank was editor of *Imago* and *Internationale Zeitschrift für Psychoanalyse*, the first European journals on psychoanalysis, from 1912 to 1924; in 1919 he founded the Internationale Psychoanalytische Verlag, of which he was director until 1924. Freud endorsed and freely quoted Rank's earlier contributions, but violently opposed the more original theories developed in Rank's last important book, *Das Trauma der Geburt* (1924; Eng. trans., *The Trauma of Birth*, 1953). Consequently they parted company. After leaving Vienna in 1924 Rank divided most of his time between Paris and the United States, being engaged chiefly in teaching and in psychotherapeutic work. In 1936 he finally settled in New York city. There he sought to modify the Freudian theory, which had developed under the social conditions formerly prevailing in Vienna, and to adapt it to the contemporary needs of an industrial society, like that in the United States. He died on Oct. 31, 1939, five weeks after Freud.

See J. Jones, "Otto Rank: a Forgotten Heresy," *Commentary*, 30: 219–229 (September 1960). (Cv. B.)

RANKE, LEOPOLD VON (1795–1886), the leading German historian of the 19th century, whose scholarly method and way of teaching (he was the first to establish a historical seminar) had a great influence in England and the United States, was born into a family of Lutheran pastors and lawyers on Dec. 21, 1795, in Wiehe, Thuringia, in the kingdom of Saxony. At Schulpforta (see PFORTE) and Leipzig University he studied classics and theology and learned to use medieval sources. From 1818, when he became a teacher in Frankfurt an der Oder, to the end of his life, he worked in the service of Prussia, in 1825 being appointed assistant professor and in 1834 professor in Berlin. He was ennobled in 1865, and died on May 23, 1886, in Berlin.

BY COURTESY OF ARCHIV FÜR KUNST UND GESCHICHTE, BERLIN
LEOPOLD VON RANKE, PORTRAIT BY JULIUS SCHRADER

Ranke combined pietistic Lutheranism with Johann Fichte's idealism and a philosophy of humanity inherited from Johann Herder and Goethe; he united the 18th-century concept of universal history with the Romantic doctrine of individualism and organic development. His characteristic quality appears in his declaration of war on the moralizing and utilitarian history of the Enlightenment: he tries to discover how things really were but fits his empirical analyses into a personal view of the universe. The western community of Latin and Germanic peoples, the link between Christian and humanist cultural values, and the hidden rule of world history by the Christian God are basic concepts in his historical way of thinking. Thus his first work, the *Geschichten der romanischen und germanischen Völker, 1494–1535* (1824; English translation, *History of the Latin and Teutonic Nations*, 1887), which opened the door to 50 years' teaching at the University of Berlin, became his "program"; the two shorter studies *Die grossen Mächte* and *Das politische Gespräch* (1833 and 1836 respectively) contain the historical and philosophical creed which he expanded in his later great works. Objective research and personal belief in a realm of ideas standing, in the Platonic sense, behind the world of appearances, gave him his grasp of the historical interplay of the general and particular.

His philosophy of history is not systematic but seems full of paradoxes; he wanted, on the one hand, to exclude himself, yet felt himself, as a priest in the service of truth, to be endowed with full personal responsibility; he worked critically and yet judged intuitively; he rejected metahistorical speculation (as in Hegel, e.g.) but his writings are saturated in religious values.

His urge toward harmonization was so great that with all his knowledge of political history he concealed the abysses of political power and aggression. The state became for him an ethical concept, a partner morally equal to the church, only conceivable in its particular historical and national character. He thus introduced a deviation from the generalized thinking common to Western Europe based on natural law, a deviation which was long influential in Germany, being still more emphasized by the founding of the empire under Bismarck. It is true that his preference for diplomatic history allowed him to lay bare the national components of the European state system; the particular character of internal political and cultural events, as well as religious factors, were also taken into consideration. But the social and economic aspects of historical life receded into the background and even political passions only appeared in a muted form. He was excellent at character studies, particularly in the early work *Die römischen Päpste, ihre Kirche und ihr Staat* (1834–36; Eng. trans. 1840)—a book which received its counterpart in *Deutsche Geschichte im Zeitalter der Reformation* (1839–47); but he wanted biography to be understood as a part only of the wider struggle of ideas and forces, and personalities only as the vehicles of powers beyond the individual. He found the centre of gravity of modern European times in the changing relationship of church and state and finally in the concert of the great powers. His national histories (*Neun Bücher preussischer Geschichte*, 1847–48, Eng. trans. 1849; *Französische Geschichte*, 1852–61; *Englische Geschichte*, 1859–68) concentrate on the 16th and 17th centuries and the development of the modern state; and they describe the development of national feeling as a problem of European history (whose Slav components he incidentally neglected). His leit-motivs are the system of states and the concept of the European balance of power, which prevented the hegemony of any individual nation. He had identified himself too completely with the middle class and aristocratic order of society which belonged to the Prussia of his day, and was too friendly toward the ideas of Frederick William IV, to be as just toward the forces of revolution as toward those of restoration. As a mainly contemplative scholar he also lacked the political drive toward action—which was one reason for the failure of the *Historisch-Politische Zeitschrift*, which on behalf of the government he edited for a few years (1832–36).

In later life he turned once more to the dream of his youth—to write a universal history. It remained a fragment (*Weltgeschichte*, 1881–88), hardly going beyond the emperor Henry IV (the history was posthumously brought up to the end of the 15th century on the basis of Ranke's notes), and displaying a viewpoint which the events of his time had already made antiquated. As Ranke was prevented by his predilection for the *ancien régime* from including the history of the British Empire, the United States, or Russian expansion in his writing, or even from dealing with the growth of modern industrial society (which had, after all, already begun in England), his picture of world history was confined to the Mediterranean and the continent of Europe. The result was to narrow the outlook of generations of German historians. Nonetheless, his influence extended far beyond the frontiers of Germany, and he is to be accounted one of the creators of modern historical method. Even his first work on the Latin and Germanic peoples contained a "criticism of modern historians" (i.e., of the Renaissance); he then revealed as the most valuable source of his historical insight the reports of 16th- and 17th-century Venetian ambassadors. Ranke devoted himself to this diplomatic school and became an expert archivist, helped by journeys to Vienna and Italy, which were arranged by the Prussian government (1827–31). He also profited at this period by meeting politicians like Friedrich Gentz, Metternich's publicist, gaining insight into contemporary foreign policy, particularly with regard to the Eastern Question. But his concern with the southeastern European states under Turkish rule—a concern whose fruit was his *Geschichte der Revolution in Serbien* (1829; Eng. trans., *A History of Servia*, 1847)—was only an episode: he turned to the documentary study of the 16th and 17th centuries and to the rise of the great powers. Only occasionally (in essays for the *Historisch-Politische Zeitschrift*, in a few lectures, in a biographical

article on Frederick William IV, and in his *Aus dem Briefwechsel Friedrich Wilhelms IV mit Bunsen*, 1873) did he return to contemporary politics. When he did it was especially with a view to warning against dogmatic liberalism. His *Neun Bücher preussischer Geschichte* (1847–48; Eng. trans., *Memoirs of the House of Brandenburg*, 1849), later expanded to 12 books (1878), is a justification of the historical role of Prussia.

He was not a brilliant lecturer but his seminars were a pattern of methodical analysis of sources and the empirical formation of judgments. He was constantly attacked by other historians for his political quietism. As an organizer, he performed an immense service in the foundation of the *Historische Kommission bei der Bayerischen Akademie der Wissenschaften*, which King Maximilian II undertook in 1858 at his instance. He presided over the commission's editions of documents, charters, chronicles, and letters as well as over such works as the *Allgemeine Deutsche Biographie* and the *Geschichte der Wissenschaften in Deutschland*. His most valuable legacy, however, was probably the conquest of historical relativism through his religious reverence and his highly personal blending of knowledge and belief. For Acton he was "almost the Columbus of modern history." See also HISTORY: *Historiography*.

BIBLIOGRAPHY.—For the best bibliographical approach, with list of English translations, see Theodore H. von Laue, *Leopold Ranke, The Formative Years* (1950). Editions: *Sämmtliche Werke*, 54 vol. (1867–90). The edition undertaken by Paul Joachimsmen for the Deutsche Akademie (critical edition of the *Reformationsgeschichte* and the *Preussischer Geschichte*) remains a fragment (1925 ff.). The *Weltgeschichte* was published separately, in 9 parts (1881–88). See also *Leopold von Ranke, Das Briefwerk*, ed. by W. P. Fuchs (1949); *Leopold von Ranke, Neue Briefe*, collected by B. Hoefft and H. Herzfeld (1949). For recent opinion see Rudolf Vierhaus, *Ranke und die soziale Welt* (1957); E. Kessel, "Rankes Auffassung der amerikanischen Geschichte," *Jahrbuch für Amerikastudien*, VII (1962). (Fz. W.)

RANKINE, WILLIAM JOHN MACQUORN (1820–1872), Scottish engineer and physicist, best known for his research in molecular physics and as one of the founders of the science of thermodynamics, was born in Edinburgh on July 5, 1820, and educated at Edinburgh University. Trained as a civil engineer under Sir John B. MacNeill, he was appointed in 1855 to the Queen Victoria chair of civil engineering and mechanics in Glasgow University. One of Rankine's first scientific works, a paper on fatigue in metals of railway axles, was the pioneer English paper in this field; its publication in 1843 led to new methods of construction. Rankine's *A Manual of the Steam Engine and Other Prime Movers* (1859) is a classic. The Rankine cycle, named after him, is a thermodynamic cycle of events used as a standard for the performance of steam-power installations where a condensable vapour provides the working fluid. In soil mechanics his work on earth pressures and the stability of retaining walls was a notable advance. Rankine's greatest paper was "On the Thermodynamic Theory of Waves of Finite Longitudinal Disturbance." Other subjects in which he became interested included propellers, the lines of ships, and streamlines. The catalogue of the Royal Society, of which he became a fellow in 1853, lists 154 of his papers; some were reprinted as *Miscellaneous Scientific Papers* (1881). Rankine died in Glasgow on Dec. 24, 1872. (A. McD.)

RANSOM, JOHN CROWE (1888–), U.S. poet and critic, was born on April 30, 1888, in Pulaski, Tenn. Graduated from Vanderbilt University, Nashville, Tenn., in 1909 and from Oxford, where he was a Rhodes scholar, in 1913, he taught English at Vanderbilt from 1914 to 1937, when he went to Kenyon College, Gambier, O., as professor of poetry and editor of the *Kenyon Review*.

From 1922 to 1925, Ransom and his pupils—Donald Davidson, Allen Tate, Merrill Moore, and Robert Penn Warren—published a magazine of their own verse called *The Fugitive*. The same group (excepting Moore), joined by others at Vanderbilt, published *I'll Take My Stand* (1930), which criticized current notions of industrial progress. Ransom turned to literary criticism in *The World's Body* (1938) and *The New Criticism* (1941), the latter of which gave the name to the critical school that is concerned with the close reading of poetical texts. Ransom's poems, collected in *Chills and Fever* (1924), *Two Gentlemen in Bonds* (1926), and

Selected Poems (1945), are remarkable for their wit and irony, their understatement, and their Southern urbanity. (R. St.)

RANTOUL, a village of Illinois, U.S., in Champaign County, was incorporated in 1869 and named for Robert Rantoul, an early member of the board of directors of the Illinois Central Railroad. Located about 15 mi. (24 km.) NE of Champaign in the grand prairie of east-central Illinois, the village originally had an agricultural economy. Chanute Air Force Base, adjacent to Rantoul, was built in 1917 and has been permanent since 1921. Building and maintenance of the base provided new and varied opportunities for employment to local people. School-building programs received federal aid; churches and recreational facilities were also provided. Residential development, largely to accommodate air force personnel, contributed to changing this rural community into an urban one.

For comparative population figures see table in ILLINOIS: *Population*. (T. J. T.)

RANUNCULACEAE, a plant family of the order Ranales that includes many familiar and ornamental flowers. There are 30 genera with about 700 species in temperate and cold regions, especially in the northern hemisphere. The family contains many well-known forms, such as buttercup, larkspur, anemone, columbine, clematis, marsh marigold, peony, etc. In North America there are about 25 genera, in Great Britain 12. The plants are dicotyledons (*i.e.*, with two seed leaves), and the family retains many of the primitive characters of the extinct ancestors of the higher dicotyledons and monocotyledons. Most of the plants are herbs (rarely woody vines, as in some species of *Clematis*) with alternate leaves (opposite in *Clematis*) usually without stipules. The flowers, which show considerable variation in the number and development of parts, are characterized by free hypogynous sepals and petals, numerous free stamens, usually many free one-chambered carpels and small seeds containing a minute straight embryo embedded in a copious endosperm. The parts of the flower commonly are arranged spirally on a convex receptacle. The fruit is one-seeded (an achene) or many-seeded (a follicle) or rarely, as in *Actaea*, a berry.

The family falls into well-defined tribes distinguished by characters of the flower and fruit.

Tribe I, Paeoniaceae (peonies), are mostly herbs with deeply cut leaves and large solitary showy flowers in which the parts are arranged spirally, the sepals, generally five in number, passing gradually into the large coloured petals. There are two to five free carpels which bear a double row of ovules along the suture. There are no special stalked nectaries, but nectar is secreted by a ringlike swelling around the bases of the carpels. The pistils become fleshy in the fruit and each dehisces along the suture. There are only three genera; the largest, *Paeonia*, occurs in Europe, temperate Asia and western North America. *P. officinalis* is the common peony; *P. suffruticosa* is the tree peony, native to China. This tribe possibly constitutes a separate family.

Tribe II, Helleboreae, are almost exclusively north temperate or subarctic. The leaves may be entire or nearly so, as in *Caltha*, but more often palmately divided as in hellebore, aconite (monkshood) and larkspur. The flowers are solitary (*Eranthis*) or in cymes or racemes, and are radially symmetrical as in *Caltha* (marsh marigold), *Trollius* (globeflower), *Helleborus* (hellebore), *Aquilegia* (columbine) or sometimes bilaterally symmetrical as in *Aconitum* (aconite) and *Delphinium* (larkspur). The carpels, generally three to five in number, form in the fruit many-seeded follicles, except in *Actaea* (baneberry), where the single carpel develops into a many-seeded berry, and in *Nigella*, where the five carpels coalesce, forming a five-chambered ovary. The sepals are usually five and are white or brightly coloured. Thus in *Caltha* and *Trollius* the sepals form a brilliant golden-yellow globe, and in *Eranthis* a pale-yellow star; in *Nigella* they are blue or yellow. In *Helleborus* the greenish sepals persist until the fruit is ripe. *Aconitum* and *Delphinium* differ in the bilaterally symmetrical development of the sepals, the posterior one being distinguished from the remaining four by its helmet shape (*Aconitum*) or by its spur (*Delphinium*). In *Trollius* the petals are long and narrow with a honey-secreting pit at the base; in *Nigella* and *Helleborus*

they form short-stalked pitchers; in *Aquilegia* they are large and coloured with a showy, petallike upper portion and a long basal spur in the tip of which is the nectary. In *Delphinium* they are also spurred, and in *Aconitum* they form a spurlike sac on a long stalk. The parts of the flower usually are arranged in a spiral (acyclic), but are sometimes hemicyclic, the perianth forming a whorl as in winter aconite; rarely is the flower cyclic, as in *Aquilegia*, in which case the parts throughout are arranged in alternating whorls. In *Caltha*, where there are no petals, nectar is secreted in two shallow depressions situated on the side of each carpel. Monkshood is a source of medicinal febrifuges.

Tribe III, Anemoneae, are chiefly temperate, arctic and alpine herbs. They differ from the two preceding tribes in the usually numerous carpels, each with only one ovule, forming achenes. The subgenus *Batrachium* of the genus *Ranunculus* (*q.v.*) contains aquatic plants with submerged or floating stems and leaves. The flowers are solitary as in *Anemone pulsatilla* (pasqueflower), cymose as in species of *Ranunculus*, or in racemes or panicles as in *Thalictrum*. The parts are arranged spirally throughout as in *Myosurus* (mousetail), where the very numerous carpels are borne on a much-elongated receptacle, or the perianth appears whorled as in *Anemone* and *Ranunculus*. In *Anemone* and *Thalictrum* there is only one series of perianth parts, and these are petaloid and attractive in *Anemone*, in which nectar is secreted by modified stamens. In *Anemone nemorosa* (European wood anemone), there is no nectar and the flower is visited by insects for pollen; in *Thalictrum* the perianth is greenish or slightly coloured, and the flower is wind-pollinated (*T. minus*) or visited for its pollen. On the petal of *Ranunculus* there is a basal nectary usually covered by a scale. In *Anemone* the achenes bear the persistent naked or bearded style which aids in dissemination; the same purpose is served by the prickles on the achenes of *Ranunculus arvensis*. *Clematis* (*q.v.*) is characterized by its shrubby, often climbing habit, opposite leaves and the valvate (not imbricate as in the rest of the family) estivation of the sepals. The fruit consists of numerous achenes prolonged into the long feathery style, whence the popular name of the British species, old-man's-beard (*Clematis vitalba*).

See also ACONITE; ADONIS; ANEMONE; BANEERRY; CIMICIFUGA; CLEMATIS; COLUMBINE; HELLEBORE; LARKSPUR; RANUNCULUS, etc.

BIBLIOGRAPHY.—L. Benson, *Plant Classification* (1957); A. Engler and K. Prantl, *Die natürlichen Pflanzenfamilien* (1887–1908); G. H. M. Lawrence, *Taxonomy of Vascular Plants* (1951). (L. Bn.)

RANUNCULUS, familiarly known as buttercup, or crow-foot, a characteristic genus of the botanical family Ranunculaceae (*q.v.*). The Latin name, which means a little frog or tadpole (diminutive of *rana*, frog), was also given to a medicinal plant, which has been identified by some with the crowfoot. The members of the genus *Ranunculus* are more or less acrid herbs, sometimes

RUTHERFORD PLATT
RANUNCULUS, COMMONLY KNOWN AS BUTTERCUP OR CROWFOOT. PETALS AND SEALS HAVE BEEN REMOVED FROM FLOWER AT LEFT SHOWING THE PISTIL AND STAMENS

with fleshy root fibres, or with the base of the stem dilated into a kind of tuber (*R. bulbosus*). They have tufted or alternate leaves, dilated into a sheath at the base, and generally, but not universally, deeply divided above. The flowers are solitary, or in loose cymes, and are remarkable for the number and separation of their parts. Thus there are five sepals, as many petals, and numerous spirally arranged stamens and carpels. The petals have a little nectary or honey gland at the base. The fruit is a head of achenes—dry, one-seeded fruits.

The genus contains a large number of species (about 250) and occurs in most temperate countries in the northern and

southern hemispheres, extending into arctic and antarctic regions, and appearing on the higher mountains in the tropics. Inclusive of the water buttercups, 100 native species of *Ranunculus* occur in North America, widely distributed throughout the continent. Representative species are *R. septentrionalis*, *R. abortivus* and *R. recurvatus*, of the eastern states, and *R. californicus* of the Pacific coast. About 15 species are found in Great Britain. *R. acris*, *R. repens* and *R. bulbosus* are the common buttercups. *R. arvensis*, which is found in European cornfields, has smaller pale-yellow flowers and the achenes covered with stout spines.

R. lingua and *R. flammula*, the spearwort, grow in marshes, ditches and wet places. *R. ficaria* is the pilewort or lesser celandine, an early spring flower in European pastures and waste places, characterized by having heart-shaped entire leaves and clusters of club-shaped roots.

The section *Batrachium* comprises the water buttercups, denizens of pools and streams, some of which vary greatly in the character of the foliage according to whether it is submerged, floating or aerial, and when submerged varying in accordance with the depth and strength of the current.

The ranunculus of the florist is a cultivated form of *R. asiaticus*, a native of the eastern Mediterranean Levant region, remarkable for the range of colour of the flowers (yellow to purplish black) and for the regularity with which the stamens and pistils are replaced by petals forming double flowers.

RANVIER, LOUIS ANTOINE (1835–1922), French histologist, a master of technical methods and a true scientist, one of the great French biologists, was born on Oct. 2, 1835, at Lyons. He began his medical studies in Lyons and worked in the hospitals there under such well-known clinicians as Charles Jacques Bouchard and Raphaël Lépine. He was appointed intern in the Paris hospitals in 1860 and graduated M.D. five years later, presenting a thesis on the development and diseases of bone. By this time he had formed a close friendship with André Victor Cornil (1837–1908), with whom he shared an intense interest in the rapidly developing science of histology. The two friends opened a private laboratory where they gave special courses for students. Cornil soon obtained academic promotion, and Ranvier, having attracted the attention of Claude Bernard, was appointed his assistant in 1867. In 1869–76 Cornil and Ranvier brought out their *Manuel d'histologie pathologique*, a revelation to their contemporaries and one of the landmarks in 19th-century medicine. In 1872 a special histological laboratory was opened for Ranvier at the Collège de France, and in 1875 he became the first occupant of the chair of general anatomy.

Apart from the *Manuel* Ranvier's most important published works were his *Traité technique d'histologie* (1875 ff.), *Leçons sur l'histologie du système nerveux* (1878) and *Leçons d'anatomie générale, faites au Collège de France* (1880–81). He also wrote many papers and edited seven volumes of the *Travaux* of his laboratory (1874–88). His own researches were concerned particularly with the histology of nerve fibres, the regeneration of nerves, the bipolar nature of ganglionic cells and the minute structure of the skin, conjunctival tissue and cornea. In 1878 he first described the constrictions seen in medullated nerve fibres which are known as the nodes of Ranvier. He was elected a member of the Académie de Médecine (1880) and of the Institut (1887). During his pioneer researches Ranvier had many pupils and disciples, but in the period 1880–85 the interest aroused by Louis Pasteur's discoveries in bacteriology led to a decline in histological studies. Ranvier's laboratory was no longer frequented, his courses lapsed and he made few further contributions to science. Thereafter he spent most of his time on an ancestral estate at Vendrages (Loire), to which he finally retired c. 1900, occupying himself with country pursuits. He never married, and in his later years was a solitary figure.

Ranvier died on March 22, 1922, leaving part of his fortune to the town of Roanne for the erection of a sanatorium for tuberculosis.

RAOULT, FRANÇOIS MARIE (1830–1901), French chemist, best known in connection with work on solutions (*q.v.*), was born at Fournes, Nord, on May 10, 1830. In 1862, after hold-

ing various teaching posts, he became professor of chemistry in the *lycée* at Sens. In 1867 he was put in charge of the chemistry classes at Grenoble, and three years later he succeeded to the chair of chemistry, which he held until his death on April 1, 1901. In his doctoral research on the heat of reaction and electromotive force of galvanic cells, he made the important observation that the two did not correspond on the theory that heat is a measure of affinity.

One of his most important contributions was the discovery that the freezing point depression of aqueous solutions is proportional to the solute mole fraction. His most valuable finding (Raoult's law) was the discovery that the vapour pressure of the solvent in a solution is proportional to the mole fraction of the solvent. Raoult's law has been of fundamental importance in the development of the theory of solutions.

RAPALLO, a resort on the Riviera di Levante in Genova (Genoa) Province, Liguria, Italy, 19 mi. (30 km.) SE of Genoa by road and rail. It gives its name to the Gulf of Rapallo (or Golfo Tigullio) on which it is situated. Pop. (1961) 21,740 (commune). There is a 15th-century castle and a 12th-century church. Many new tourist accommodations were built after World War II, and tourism is the main activity. Attractions include water sports, golf, go-kart racing, skiing (on artificial snow), art and folklore exhibitions, and winter concerts; and there is an international library.

Rapallo is on the direct road and rail routes from Rome to the Italian and French rivieras. Pillow lace, textiles, and cement are made. First mentioned in 964, Rapallo was sacked successively by Longobards, Normans, and Swiss. It became a city in 1956.

(G. RA.)

RAPALLO, TREATY OF, the symbol of a sensational *rap-prochement* between two of the defeated states of World War I, was signed on April 16, 1922, during the Conference of Genoa (*q.v.*), by Walther Rathenau, foreign minister of the German republic, and Georgi V. Chicherin, people's commissar for foreign affairs of the Russian Soviet Federated Socialist Republic. On Nov. 5, 1922, the treaty was extended to other republics of the U.S.S.R.

The treaty stipulated that full diplomatic and consular relations between the two countries should be immediately resumed; that Germany and Russia renounced reciprocally all claims to war reparations of any sort, including payment for the maintenance of prisoners of war; that Germany renounced any compensation for losses incurred by German subjects in consequence of Russian nationalization of private property "provided that the Soviet government does not satisfy similar claims of other states"; and that "most-favoured-nation" treatment should apply to mutual trade relations.

The Treaty of Rapallo, negotiated in great secrecy but published the day after its signature, was not a foundation of a German-Soviet alliance, though both sides wanted to raise the bogey of such an alignment. Rathenau's adviser, Baron Ago von Maltzan, known as "the Red Baron," wanted more: he was hoping that eventually, with Soviet help, Germany would be able to restore the German frontier of 1914 in Eastern Europe. The main result of the treaty was that Germany was able secretly to build and test in Russia new prototypes of weapons forbidden by the Treaty of Versailles; thus the *Reichswehr* could develop new heavy guns, new tanks, new military aircraft, and even experiment with poison gas in Russia. The high command of the Red Army gladly agreed to the arrangement on condition that the prototypes should not leave Russia and that the Red Army should be fully informed of the test results. An English version of the text of the treaty is printed in *Papers Relating to International Economic Conference, Genoa, April–May 1922*, Cmd. 1667 (1922).

(K. SM.)

RAPE, various plants of the genus *Brassica* (mustard family, Cruciferae), the source of oil-yielding rape seed. Most of the cultivated varieties appear to belong either to *Brassica napus* or *B. campestris*. Both may be grown as annuals or biennials, depending upon the variety and the time of sowing. *B. napus* is a much-branched, glaucous plant growing to 3½ ft. tall, with lobed or toothed, succulent leaves, yellow flowers and elongate narrow pods.

B. campestris is similar, but it is more weedy, its leaves are less succulent and the plant is less glaucous. Leading producers of rape seed are China, India, Pakistan, Japan, Sweden, France and the U.S.S.R. Some rape is grown for seed in Canada, but in the United States the plant is used mainly as a forage and green manure crop.

Rape-seed oils are used mainly as edible oil and in lubricants. (J. W. Tr.)

RAPE, in law, is the crime committed by a man in obtaining unlawful carnal knowledge of a woman, without her consent, by fear, force, or fraud. A husband cannot commit rape upon his wife unless she is legally separated from him.

A felony at common law, rape was reduced in England to a misdemeanour in 1275, but in 1285 was again declared a felony, with benefit of clergy, and so remained until 1575, when the punishment was made more severe. It became a capital offense by the Offences Against the Person Act, 1861, and is now punishable with imprisonment for life. The law of England regards as immaterial whether the woman is chaste or unchaste, married or single. The offense is complete if consent is extorted by threats of death or immediate bodily harm, by fraud or by false pretenses, or by personating the woman's husband.

In the United States the elements of the crime under statute are similar to those at common law. The age when effective consent can be given by the woman has commonly been set by the various states between 14 and 18 years. Want of age on the part of the man is not a defense, as at common law, but simply presumptive evidence of lack of physical capacity. Many states require the testimony of the woman to be corroborated by other evidence and require the prosecution to be initiated within a year or less after the commission of the offense. The punishment is usually imprisonment, though a number of states, especially in the South, prescribe or permit death as the penalty. (P. E. L.)

RAPHAEL (Heb. "God heals"), one of the archangels, in the Old Testament apocryphal Book of Tobit, he who in human disguise and under the name of Azarias ("Yahweh helps") accompanied Tobias in his adventurous journey and conquered the demon Asmodeus. He is said (Tob. xii, 15) to be "one of the seven holy angels [archangels] who present the prayers of the saints and enter into the presence of the glory of the Holy One." In the Book of Enoch (ch. xx) Raphael is "the angel of the spirits of men," and it is his business to "heal the earth which the angels [i.e., the fallen angels] have defiled." Though the archangels are referred to as numbering seven (e.g., Rev. viii, 2 and Tob. xii, 15), only four are named (in the Book of Enoch): Michael, Uriel, Suriel (Raphael) and Gabriel. Raphael is reckoned among the saints in both Eastern and Western churches, his feast day being Oct. 24. See also ANGEL.

RAPHAEL (RAPHAELLO SANTI OF SANZIO) (1483–1520), one of the greatest Italian painters of the Renaissance, was born in Urbino, the son of Giovanni Santi. His birth, probably on April 6, 1483, took place in a house which still contains a fresco of the "Madonna and Child" that is either by his father or is a very early work of his own. Giovanni Santi was not a very good painter, as may be seen from his surviving works such as the "Madonna and Child With Saints" (1489, Urbino gallery), but he presumably gave Raphael his first grounding as a painter. He died in 1494, and, as Raphael's mother had already died in 1491, parental influence can have counted for little. What was far more important was Urbino itself, for this little hill town was one of the most civilized in Europe in the 15th century, under its Duke Federigo da Montefeltro and his son and successor Guidobaldo. The palace is one of the masterpieces of Italian architecture; Piero della Francesca had worked in Urbino in the 1460s and 1470s; Bramante was a citizen and was later to play a major part in Raphael's career; and Baldassare Castiglione, the arbiter of manners and author of *The Courtier*, was an Urbinate. The latter was to become a friend of Raphael, whose portrait of him (1516, Louvre, Paris) is one of the first modern portraits—a study of character distinct from that accumulation of details which the 15th century had regarded as essential to portraiture.

Earliest Works.—Raphael's earliest years are still obscure. He is first recorded on Dec. 10, 1500, when he shared in a commission for a "St. Nicholas," completed on Sept. 13, 1501, which is now lost but is known in part through drawings. Extant works which are probably of this very early period include the large "Mond Crucifixion" (National gallery, London) and the two tiny panels of the "Knight's Dream" (also National gallery) and the "Three Graces" (Chantilly, France). Before this time he had almost certainly assisted Perugino in his frescoes in the Sala del Cambio at Perugia, and for the next few years the influence of Perugino was dominant; indeed, Raphael might well have settled down to succeed to Perugino's business had it not been for his visit to Florence which fertilized his imagination. The figure of Fortitude in the Sala del Cambio is usually agreed to be by Raphael's hand, but here, of course, he was merely executing Perugino's cartoon. Between 1501 and 1503 Raphael was commissioned to paint an "Assumption" for the nuns of Monteluce, but the picture (now in the Vatican gallery) was actually finished after his death by his pupils. The earliest surviving work by him that is completely certain is the "Spasializio," or "Marriage of the Virgin," which is signed and dated 1504 (Brera gallery, Milan). The types are markedly Peruginian and the composition derives from Perugino's "Christ Giving the Keys to St. Peter" (Sistine chapel, Vatican) and from another "Spasializio" attributed to Perugino, now in the museum at Caen, France. It has, however, been suggested that the Caen picture derives rather from Raphael; what is certain is that the Brera "Spasializio" is no more than an improved Perugino and falls short of the great masterpieces Raphael was to paint no more than five years later.

Florentine Period.—Probably late in 1504 Raphael went to Florence, and this date marks the first decisive phase in his career. By 1505 he was once again in Perugia, where he was commissioned to paint a fresco in S. Severo; this seems to have been still unfinished at his death and was completed by his former master Perugino, who outlived him. Nevertheless, the upper part of the fresco contains the germ of his first great Roman work, the "Disputa." Probably immediately after he received this commission Raphael returned to Florence, where he set himself to relearn his whole art under the influence of the two greatest living artists, Leonardo da Vinci and Michelangelo, both then in Florence. Also, he became friendly with Fra Bartolommeo (*q.v.*), but here the influence was mutual. A series of Madonna compositions (Florence, Paris, Vienna, Washington, D.C., and elsewhere) shows Raphael learning the Florentine method of building up his composition in depth with pyramidal figure masses, with figures grouped as a single unit, yet each retaining its own individuality of character and shape. This new sense of unity in composition and the suppression of inessential details he owed mainly to Leonardo, in particular to his "Madonna and Child and St. Anne" cartoons. To Leonardo he also owed a new sense of softness in modeling and skill in chiaroscuro, shown in his portraits of Angelo and Maddalena Doni (Pitti, Florence), in which he adapted the model provided by Leonardo's "Mona Lisa." To counterbalance any tendency to imitate the slightly overripe quality of Leonardo's modeling, Raphael made a profound study of Michelangelo's cartoon of the "Battle of Cascina," with its stress on dramatic action and expressive anatomy. The "Ansidei Madonna" (*c.* 1506, National gallery, London) shows something of both these influences, but the full impact of Michelangelo on Raphael at this date is best seen in the "Borghese Entombment" (1507, Borghese gallery, Rome), painted for Atalanta Baglione of Perugia in memory of her murdered and murderous son. It contains several more or less direct quotations from Michelangelo and there can be no doubt that in it and other works of the same period Raphael set himself deliberately to learn from Michelangelo the expressive possibilities of human anatomy.

Roman Period.—On April 21, 1508, Raphael was still in Florence, as we know from a letter of that date, and the "Cowan Madonna" (National Gallery of Art, Washington, D.C.) is signed and dated 1508 and must therefore be one of his last Florentine works. Traditionally it was Bramante who summoned him to Rome, since he was distantly related to Raphael and knew

BY COURTESY OF (TOP) THE SMITHSONIAN INSTITUTION, (RIGHT) NATIONAL GALLERY OF ART, WASHINGTON D.C., MELLON COLLECTION

that there were good commissions to be had from his own splendid patron, Pope Julius II. The tradition is the more likely to be correct in that Raphael was still virtually an unknown provincial painter, by no means yet the third member of the Leonardo-Michelangelo-Raphael triumvirate that springs automatically to the mind. He was still only in his middle 20s, but he was soon to receive a commission from the irascible but extremely discerning pope that placed him practically on a level with Michelangelo. Raphael was certainly at work in the Vatican by Jan. 13, 1509, and on Oct. 4 of that year he was granted a papal sinecure, presumably in payment for work done in the Stanze (Italian, "rooms").

The Stanze.—Julius II, who detested the memory of his predecessor Alexander VI, refused to use the Borgia apartments and, as a consequence of his remodeling of the Vatican palace, Bramante built the Cortile di S. Damaso, later to be completed by Raphael and decorated by his pupils under the name of "Raphael's Loggia." As his first great work for the pope, Raphael was commissioned to paint a cycle of frescoes in a series of medium-sized rooms known simply as the Stanze. The Stanza della Segnatura and Stanza d'Eliodoro are practically entirely decorated by Raphael himself; the Stanza dell' Incendio, though designed by Raphael, was largely executed by his numerous assistants and pupils; the last and largest of the apartments, the Sala di Costantino, was hardly even designed by Raphael, and was not finished until about four years after his death.

The main themes of the Stanze are fairly simple and easily grasped, but the details of the iconography have never been completely worked out since no two scholars are satisfied with the same interpretations. It is highly probable that there was a written "program" for the series as a whole and perhaps also for each fresco, but it has not survived and the two most important questions are left unanswered: to what extent was it imposed on Raphael by the pope or his advisers, and to what extent was each and every detail of each fresco charged with a meaning that had been worked out in advance? When Raphael arrived in Rome he was young, almost unknown, and certainly not particularly well educated in the humanist sense; yet long before he died he was famous not only as a painter but also as a scholar and was clearly on easy and familiar terms with the papal court in general. The most likely reason for this is that he had shown himself the ideal humanist artist; that is, he was able to devise great works of

art which at the same time were heavily charged with allegorical or symbolic meaning. One example will perhaps make this clear. The figures of Plato and Aristotle in the fresco known as the "School of Athens"—the identity of these two figures is shown by the books they hold—are not only exactly right from the formal point of view, as two contrasted figures set in the optical centre of the composition, but also the simplest and most telling visual symbols of the two contrasted philosophies. Plato is a grave old man, pointing upward as though to emphasize the heavenly origin of those Ideas which are the basis of his philosophy; Aristotle, a much younger and more vigorous man, gestures in a decisive and forthright way toward the earth as an expression of his unidealistic philosophy.

The four Stanze consist of a single enfilade of rooms, the first three (in the order in which the visitor sees them) being those of

the Fire in the Borgo (dell' Incendio), of the Tribunal (della Segnatura) and of Heliodorus (d'Eliodoro). Each of these is about 30 ft. by 25 ft. in size, but the last and largest room, the Sala di Costantino, is about 30 ft. by 45 ft. It communicates directly with the Loggia di Raffaello.

The first to be painted was the Stanza della Segnatura, frescoed between 1509 and 1511. It seems to have been used for the sittings of a legal tribunal, and its title implies that important state documents were signed or sealed in it. The ceiling is decorated with four roundels and four rectangular panels in imitation of mosaics, representing Theology, Justice, Philosophy and Poetry (in the roundels), and Adam and Eve, the Judgment of Solomon, Astronomy and Apollo and Marsyas (in the rectangles). The four main fresco fields are occupied by the "Disputa" and the "School of Athens" on the larger walls and "Parnassus" and the "Cardinal Virtues" on the smaller. The two latter have subsidiary scenes representing "Augustus Preventing the Burning of the Aeneid," "Alexander the Great Depositing the Homeric Books in the Tomb of Achilles," and "Justinian Receiving the Pandects" and "Gregory IX Approving the Decretals." As the principal theme of the room is the scope of human knowledge, the main walls are given up to the contrasted representations of secular knowledge and theology—the so-called "School of Athens" and the so-called "Disputa." Presumably neither name was used by Raphael, but the "Disputa" is referred to by G. Vasari as showing "an infinite number of saints, who write down the Mass and hold dispute about the Host which is on the altar . . ." This should not be understood as meaning a dispute in the ordinary English sense of the term, but rather a medieval disputation or philosophical discussion.

It is clear that both the "Disputa" and the "School of Athens" are intended as allegories in a very general sense, and many of the highly involved "explanations" which have been propounded are no more than misplaced ingenuity. The "Disputa" is, in fact, no more than a general symbolic representation of the church on earth and in heaven, for the centre of the composition is the monstrance on the altar, with the heavenly host and the representatives of the church on earth both converging on it. At the same time the Host in the monstrance is the lowest part of the vertical axis which consists of the figures of God the Father, Christ and the Holy Spirit, again a simple piece of symbolism. The upper part of the composition is very reminiscent of the fresco

in S. Severo in Perugia, with its row of saints seated on rather solid clouds, but the lower part is more freely handled. The device of the steps, which serve to lead the eye into the picture space, and the railing at the left, balancing the awkward shape made by the door cutting into the fresco field at the right, both prove Raphael's extraordinary powers as a composer. It is very likely that this was the first time he had worked on so large a scale (something like 24 ft. across), and it is nothing short of astounding that he was able to compose the "School of Athens," one of the most subtle arrangements of a large number of figures ever painted, as his second attempt on this scale.

The "School of Athens" is perhaps the most famous of all his frescoes, as the "Sistine Madonna" is the most famous of all his Madonnas. It differs from the "Disputa" in that the symbolism is less obvious and the intention vaguer, for it represents a number of the more famous classical philosophers in a splendid basilica—based on Bramante's design for the new St. Peter's—which, in a general way, symbolizes both the dignity of philosophical enquiry and the secular nature of the subject.

At about the same time, probably in 1511, Raphael also painted a more secular subject still, the "Triumph of Galatea" in the Villa Farnesina, Rome, for the Sienese banker Agostino Chigi, for whom he was later to decorate the Chigi chapel in Sta. Maria del Popolo. The Stanza della Segnatura was completed in 1511 and Raphael began to work on the next Stanza, that of Heliodorus, in 1512, completing it in 1514. The whole character of the Stanza d'Eliodoro is entirely different from that of the Stanza della Segnatura. The generalized allegories of the "School of Athens" or the "Disputa" give way to representations of specific events, all miraculous, which, since they represent the direct interventions of God on behalf of His chosen people, had a political intention in the 16th century. The four principal subjects are: "The Expulsion of Heliodorus From the Temple," "The Miracle at Bolsena," "The Liberation of St. Peter" and "Attila the Hun Turned Back From Rome." Raphael's original patron, Julius II, died in 1513 and was succeeded by Leo X (elected March 11, 1513); as both the "Expulsion" and the "Miracle at Bolsena" (which is dated 1512) contain superb portraits of Julius II while the Leo I who is shown meeting Attila has the features of Leo X, these frescoes can be closely dated. The Stanza takes its name from the fresco of "Heliodorus Expelled From the Temple of Jerusalem" and "compassed in darkness" (II Macc. 3), which had a contemporary allusion to the efforts of Julius against the French and in support of the temporal power. The fresco of the "Mass at Bolsena" records a miracle that took place in 1263, when a priest who doubted the reality of transubstantiation found the Host bleeding in his hands; Julius' devotion to the Sacrament is probably the principal reason for the choice of this subject. The composition is one of Raphael's most accomplished, since the shape to be filled is exceedingly awkward and asymmetrical, and the celebrated group of the Swiss guards at the lower right is introduced to fill the space where it was necessary to paint a continuation of the real architecture.

In all these miraculous themes the colours are much deeper and more Venetian in feeling than the colour schemes in the earlier room, the "Liberation of St. Peter" providing a particularly notable example of the new interest in colour and light since it is a night scene and contains three separate lighting effects—moonlight, the torch carried by the soldier and the supernatural light emanating from the angel. It is usually thought that the presence in Rome at this time of Sebastiano del Piombo may have been responsible for this marked Venetian influence on Raphael, but it is also certain that Michelangelo's Sistine ceiling was unveiled while the room was in progress; yet a renewed influence of Michelangelo is not noticeable until somewhat later, most clearly in the frescoes of "Isaiah" (c. 1512, S. Agostino, Rome) and the "Sibyls" in Sta. Maria della Pace, of about 1514.

The most important other work undertaken by Raphael at this period was probably the "Sistine Madonna" (Dresden gallery), which has always been one of his most famous paintings, although its early history is unknown. The most likely explanation for its existence is that it was painted to be carried in the funeral proces-

sion of Julius II in 1513 and that it subsequently came into the possession of the monks at Piacenza who owned it before its transfer to Dresden. By 1513 Raphael was one of the most celebrated of living artists and already employed a large studio of assistants and pupils, so that it is extremely unlikely that an obscure community of monks could have commissioned a large altarpiece from him (or have got delivery if they had commissioned it).

Immediately after completing the Stanza d'Eliodoro, Raphael began work on the third Stanza, which is first in order of visiting. The Stanza dell' Incendio was begun in 1514 and completed by 1517, but the proportion of it executed by assistants is much higher than was the case in the first two rooms. Nevertheless, it must be stressed that Raphael was responsible for the decoration as a whole. The reason for this delegation of the execution is twofold: St. Peter's and the Tapestry cartoons. In August, 1514, Raphael succeeded Bramante as chief architect of the new St. Peter's, and, although he built very little of it, the administrative responsibility for the greatest work in Christendom must have been considerable. The first payment for the cartoons was made on June 15, 1515, so it is probable that this new commission had been occupying much of Raphael's attention, rather than the frescoes in the Stanza dell' Incendio. The last and largest of the Stanze, the Sala di Costantino, was commissioned in 1517 but was finished only in 1524, four years after Raphael's death.

The Tapestry Cartoons.—Leo X commissioned a set of tapestries to hang below the 15th-century fresco cycle on the walls of the Sistine chapel. Almost certainly there were 10 (10 tapestries are preserved in the Vatican museum), but a contemporary, probably by a slip of the pen, mentions 16. Seven of the original cartoons still exist in the British royal collection (on permanent loan to the Victoria and Albert museum, London) and other sets

ALINARI
"SISTINE MADONNA" BY RAPHAEL. IN THE DRESDEN GALLERY, DRESDEN, GERMANY

of the tapestries, woven at various times from the cartoons, exist elsewhere. The seven cartoons represent "Christ's Charge to Peter," "The Miraculous Draught of Fishes," "The Death of Ananias," "The Healing of the Lame Man," "The Blinding of Elymas," "The Sacrifice at Lystra" and "St. Paul Preaching at Athens"; the other three tapestries, for which no cartoons exist, are "The Conversion of St. Paul," "St. Paul in Prison" and "The Stoning of St. Stephen." The last payment was made in Dec. 1516, when the cartoons must have been sent to Brussels, where the tapestries were woven. Seven were finished by Christmas 1519 and were exhibited in the Sistine chapel, when an eyewitness wrote that "by universal consent there is nothing more beautiful in the world." They were woven by the low-warp (*basse-lisse*) method which involves reversal of the designs, so that the designer has to remember to depict right-handed actions as taking place with the left—a point which was not invariably borne in mind in the cartoons (see A. P. Oppé, "Right and Left in Raphael's Cartoons," in *Journal of the Warburg and Courtauld Institutes*, vol. vii, pp. 82 ff., 1944). It is now generally agreed that Raphael actually drew much more in the cartoons himself than was previously allowed to be the case, but the use which has been made of them and the fragile nature of the medium (size colour on paper) have combined to damage them severely in many parts. Nevertheless, the amount of damage and repainting is relatively unimportant for it cannot be too strongly emphasized that they could have been executed entirely by assistants and then completely repainted without losing their importance and value, for they are supreme examples of the art of composition. It is hardly an exaggeration to say that the normal western conception of the apostles as grave, bearded men in togas derives very largely from the visual images created by Raphael in these works. There has been a great deal of discussion about the way the tapestries were originally arranged. (For a later hypothesis see J. White and J. Shearman in *The Art Bulletin*, xl, pp. 194-222, 299-323, 1958).

By April 19, 1516, Raphael had completed the portrait of Count Castiglione, his fellow townsman and the leading authority of the day on polite behaviour. It is indicative that Raphael should have been on terms of intimate friendship with him and also with A. Navagero and other poets and at least two princes of the church, Cardinals Bembo and Bibbiena. For the latter he decorated a bathroom in his suite in the Vatican. It is in a private part of the palace and is now much damaged, but it is of interest since the decorative motifs are based on those in the newly discovered Golden House of Nero, from which the type of decoration known as "grotesque" is derived. Similar motifs were used by members of Raphael's studio, notably by Giovanni da Udine, in the stucco decorations at the Villa Madama and elsewhere. Raphael now occupied a position held by no other artist of modern times (not even Michelangelo is quite comparable), on terms of friendship with the pope and the whole Curia and with almost every prince in Christendom intriguing to obtain a work by his hand; almost overnight, the whole social position of the artist was thus revolutionized by the three great artists of the Renaissance, Leonardo, Michelangelo and Raphael. During all this time he was busy on innumerable enterprises, most of which were actually executed by his army of pupils and assistants: the remainder of the Stanza dell' Incendio, the numerous small biblical scenes in the Loggia of the Vatican (works which deserve more study than they tend to get), the sculpture and mosaics of the Chigi chapel and the work on the new St. Peter's as well as other architectural works—he designed S. Eligio degli Orefici and the Vidoni-Caffarelli and Branconio dell' Aquila palaces in Rome as well as the Palazzo Pandolfini in Florence—and the duties involved in his conservatorship of the antiquities of Rome. By employing Marcantonio Raimondi, Raphael ensured the spread of his designs all over the civilized world, for this excellent engraver produced numerous plates from designs made specially by Raphael for the purpose of spreading his ideas.

The Last Works.—A letter from Leonardo Sellaio to Michelangelo at Carrara on Jan. 19, 1517, gives the first indication of what was to become Raphael's last masterpiece, the "Transfiguration," now in the Vatican. Cardinal de' Medici (later Pope Clement VII)

commissioned two enormous altarpieces for his cathedral at Narbonne in France; one was Sebastiano del Piombo's "Raising of Lazarus" (now in the National gallery, London) and the other was Raphael's "Transfiguration," unfinished at his death and never sent to Narbonne. In fact, the "Transfiguration" was not begun until 1518 and must therefore be considered along with the "Holy Family of Francis I" and "St. Michael Vanquishing Satan" (both dated 1518 and in the Louvre, Paris), both of which were destined for presentation to Francis I of France by Leo X. All three pictures were major commissions and any new or unusual features in them are therefore extremely unlikely to be due to pupils or assistants working unsupervised; at the very least, Raphael must have approved any innovations. It is necessary, indeed, to stress this point and also to refer to the series of superb drawings for individual figures in the "Transfiguration," for there is a tendency to write off the last works, and especially the "Transfiguration," as by Giulio Romano, Gianfrancesco Penni and other pupils. Vasari noted, of the "Holy Family of Francis I," that the execution was almost entirely by Giulio Romano, and the "Transfiguration" was certainly completed after Raphael's death; yet Vasari stresses that much of it was in fact painted "with his own hand." There is every reason to suppose that the design is his, and it is in the design that the innovations are chiefly visible. The tendency in all these late works is toward a crowding together of the figures which had hitherto been lucidly arranged in accordance with the classical canons Raphael himself had done so much to impose. At the same time there is a feeling of violence and tension which is not entirely due to the demands of the subject. Indeed, one might argue that the subject was adapted to satisfy a desire to depict a scene of violence, since the boy possessed of a devil is the next stage in the Biblical narrative (Matt. 17). In short, it may be held that Raphael was the first Mannerist.

On Good Friday, April 6, 1520, after an illness lasting a week, Raphael died. He was buried in the Pantheon and his grave is marked by a slab with a commemorative epitaph by Cardinal Bembo. At the head of the bier the unfinished "Transfiguration" stood as his memorial, perhaps the first of what would have been a series of new works in the middle period which Raphael never lived to achieve. He died at 37, when most great artists are approaching their first maturity. See also PAINTING: *Raphael*; and references under "Raphael" in the Index.

RAPID CITY, a city of South Dakota, U.S., and the seat of Pennington County, is the western gateway to the Black Hills (q.v.). Located 3,200 ft. (975 m.) above sea level on Rapid Creek, from which it derived its name, it was settled in 1876 during the days of the Black Hills gold rush, and was incorporated in 1878.

Millions of tourists have been attracted by the beauty of the Black Hills, with nearby Mt. Rushmore, Crazy Horse Mountain, and Custer National Park being of particular interest. Although it is located in what is basically an agricultural and grazing area, Rapid City's industries range from lumber, millwork, and building materials to Black Hills gold jewelry. In addition, gold, silver, beryllium, feldspar, gypsum, mica, uranium, and other minerals are mined and processed in the area. Rapid City is the site of the state-owned cement plant, the Sioux Indian sanatorium, the South Dakota School of Mines and Technology (established 1885), and Ellsworth Air Force Base. For comparative population figures see table in SOUTH DAKOTA: *Population*. (C. J. P.)

RAQQAH, AR (RAKKA), a town of Syria and headquarters of the *muhafaza* (governorate) of Raqqah, lies on the east bank of the Euphrates, 100 mi. (161 km.) ESE of Aleppo. Pop. (1960) 14,554. Built by one of Alexander's generals, Seleucus Nicator, it was first named Nicephorium, and then Ar Raqqah, following the Arab conquest. Just south of the town, at Siffin on the west

bank of the Euphrates, was fought the battle which decided the caliphate in favour of Mu'awiyah in A.D. 657. Ar Raqqa was rebuilt and fortified by Harun al-Rashid, who used it as his headquarters against the Byzantines in the 8th century. Gradually the city fell into decay, and was replaced in importance by its suburb Ar Rafiqah, which took over its name. Al-Battani (Albategnius), the Arab astronomer, made his observations there between 877 and 918.

The double walls with circular towers and the castle restored by the Ottoman sultan Suleiman are still extant. The modern town lies partly within the ancient walls on the edge of the desert.

(M. V. S.-W.)

RARE EARTHS is the traditional name of the 14 metallic elements having atomic numbers 58 to 71, inclusive, and very similar chemical properties. By reference to their place in the periodic table they are known somewhat more accurately as the lanthanides or lanthanons, or the 4f elements (*see below, Structure*). The rare earths are listed in Table I. The element lanthanum (atomic number 57) is often considered the first member of the series, but a strict definition excludes it. Two other elements, yttrium and scandium, commonly occur in nature with the rare earths, which they resemble in chemical behaviour; these two elements therefore are sometimes considered along with the rare earths even though they are not members of the series.

The term "rare earths" dates from the early 19th century, when chemists obtained lanthanide substances with difficulty from relatively rare minerals and in the form of oxides resembling materials originally known as earths and thought to be elements; e.g., lime, alumina, and magnesia. In time it became known that the rare earths are widely distributed in nature, and occur in a number of concentrated minerals; they are, in fact, more abundant than some of the better-known elements. Cerium, for example, is more abundant than tin; and thulium, the rarest of the rare earths, is at least as plentiful as cadmium, silver, gold, bismuth, and the platinum metals. Among the rare earths themselves, those of even atomic numbers are five to ten times as abundant as those of odd atomic numbers. The rare earths, together with lanthanum, yttrium, and scandium, comprise about one-fourth of the known metals and one-sixth of the known elements. (*See also ELEMENTS, CHEMICAL; METAL.*) During the period of discovery of the rare earths, from 1796 to 1947, much basic information on separation techniques was obtained; and new, more efficient methods resulted from intensive research during World War II. As a result most of the rare earths are available in quantities ranging from ten pounds to many tons; by the late 1960s, known reserves of rare-earth ores totaled several million tons.

Uses.—In the past the uses of any rare earth on the basis of its individual properties were very few; the main applications arose from the properties of a mixture of several of these elements; i.e., group properties. Misch metal is an example. It is an alloy of cerium, lanthanum, neodymium, and several other rare-earth metals in their naturally occurring proportions. Because of the high activity of these metals the alloy is an excellent material for cigarette lighter flints and is also used as a deoxidizer in vacuum tubes and in metallurgy. Misch metal is also a constituent of some magnesium alloys. The use of light rare-earth oxides for Welsbach gas mantles, and of their oxides and fluorides as core material for arc-light carbons, is based upon group properties. Other uses have been based on the colour and absorptive properties the elements impart to glass and other ceramic products; e.g., didymium, a mixture primarily of praseodymium and neodymium, is extensively used for glassblowers' and welders' goggles because it absorbs the harmful radiation of sodium. The use of didymium instead of Misch metal as a constituent of magnesium alloys gives a product of greater strength at all temperatures. As alloying constituents the rare-earth metals increase the life of heating elements, the workability of stainless steels, and the oxidation resistance of certain other ferrous alloys.

As pure rare-earth metals and compounds became available, specialized uses based upon individual properties were developed. These include the use of cerium (IV) oxide, CeO₂, as a highly effective glass polish, as a constituent to increase the stability and

discoloration resistance of glass to gamma and electron-beam radiation, and as an opacifier for enamel coatings; and lanthanum oxide, La₂O₃, as a constituent of high-refraction and low-dispersion optical glass. The high melting points of the rare-earth oxides, borides, nitrides, and carbides indicate possible use as refractory materials. There is some use of certain rare-earth oxides, chlorides, and phosphates as catalysts in organic reactions. A promising field of rare-earth technology is the development of a highly efficient red-emitting cathodoluminescent phosphor, europium-activated yttrium orthovanadate, YVO₄:Eu, for use in colour television picture tubes. Certain compounds of lanthanum and yttrium show unusual electronic or magnetic behaviour and are useful in microwave devices, magnetic core materials, and ceramic capacitors, and potentially as semiconductors.

Nuclear applications, actual or potential, include the use of the elements of high absorption cross sections for thermal or slow-moving neutrons. Samarium, europium, gadolinium, and dysprosium are excellent sponges for soaking up slow neutrons and could serve as construction materials for control rods in atomic piles and for shielding and flux-suppressing devices. However, in samarium and gadolinium the absorbing isotopes are present in low concentration and burn up rapidly; they are therefore useful only in low-flux or short-time operations. Yttrium hydride, YH₃, is of use as a hydrogen-moderator carrier, and yttrium metal as a construction material in reactors, since the metal is not attacked by molten uranium at high temperature. Thulium and scandium, when suitably irradiated, serve as portable X-ray sources. Some of the properties of certain rare earths resemble those of the closely related actinide group (the elements having atomic numbers 90 to 103, inclusive); these rare earths therefore have been used as stand-ins for the radioactive and fissionable elements. For example, the use of cerium as a stand-in for plutonium and other transuranium elements permitted scientists to devise methods for separating and identifying these newly discovered elements before weighable quantities had been prepared.

Structure.—The work of British physicist H. G.-J. Moseley (*q.v.*) on the X-ray spectra of the elements had by 1914 definitely established the maximum number of rare earths and set up procedures by which they could be identified and their purity determined. Modern atomic theory and experiment have since shown that the electronic structure of each trivalent rare-earth ion is composed of a xenon core with additional electrons entering the 4f subshell, the number increasing from 1 electron in cerium to 14 in lutetium. (*See PERIODIC LAW.*) The neutral rare-earth atom contains three more electrons than the trivalent ion, one in either the 4f or 5d subshell and two in the 6s subshell. Lanthanum, which immediately precedes cerium in the periodic table, likewise is trivalent but has no 4f electrons; it is thus the structural and chemical prototype of the rare earths, and provides a name for the group of which it is not, strictly speaking, a member. (*See Table I.*)

As the nuclear charge increases from element to element in the rare-earth group the added electrons go into the underlying 4f subshell instead of into the external 5d subshell. Since the 4f

TABLE I.—The Rare Earths and Their Ionic Properties

Name	Symbol	Atomic Number	Atomic Weight	Oxidation States	Trivalent Ion		
					Number of 4f Electrons	Magnetic Moment	Ionic Radius, Å
(Lanthanum)	La	57	138.91	3	0	0.00	1.061
Cerium	Ce	58	140.12	3, 4	1	2.56	1.034
Praseodymium	Pr	59	140.907	3, 4	2	3.62	1.013
Neodymium	Nd	60	144.24	2, 3	3	3.68	0.995
Promethium	Pm	61	145*	3	4	2.83	0.979
Samarium	Sm	62	150.35	2, 3	5	1.55–1.65	0.964
Europium	Eu	63	151.96	2, 3	6	3.40–3.51	0.950
Gadolinium	Gd	64	157.25	3	7	7.94	0.938
Terbium	Tb	65	158.924	3, 4	8	9.7	0.923
Dysprosium	Dy	66	162.50	3	9	10.6	0.908
Holmium	Ho	67	164.930	3	10	10.6	0.894
Erbium	Er	68	167.26	3	11	9.6	0.881
Thulium	Tm	69	168.934	2, 3	12	7.6	0.869
Ytterbium	Yb	70	173.04	2, 3	13	4.5	0.858
Lutetium	Lu	71	174.97	3	14	0.00	0.848

*Isotope with half-life of 18 years.

electrons are screened by the completed 5s and 5p subshells, they have practically no effect on the valence forces. On the other hand the 4f orbitals are too diffuse to screen the nucleus as effectively as a completed inner shell, and the attraction of the nucleus for the outermost electrons increases with the atomic number. The net effect is a slight shrinkage in atomic size from lanthanum through lutetium—the so-called lanthanide contraction. The contraction is quite regular in the radii of trivalent ions (see Table I, last column) but somewhat irregular in the radii of the atoms.

To summarize: the trivalent ions of the rare earths and lanthanum have identical charges, identical external electronic structures, and almost the same ionic radii. Consequently their chemical properties are very similar. Since there was no place for these elements in the older periodic tables they were grouped in the space occupied by lanthanum; they are now placed in a separate series at the bottom of the table.

Yttrium (atomic number 39) and scandium (21) are just above lanthanum in transition Group III of the periodic table. Both are trivalent and have external structures like those of the rare earths. Since the chemistry of these two elements is largely ionic and is therefore determined by their ionic sizes, their behaviour closely resembles that of the rare earths. This is especially true of the yttrium ion, which, because of the lanthanide contraction, is about the same size as one of the heavier rare earths, holmium. The similarity is less close for scandium, which has a smaller ionic radius; although this element is sometimes listed with the rare earths, it is more often treated separately.

Occurrence.—Several hundred rare-earth minerals are known but only a few are commercially important. (See Table II.)

TABLE II.—Principal Rare-Earth Minerals

Mineral	Type of Ore	Leading Producers
<i>Ceria Group (Light Rare Earths)</i>		
Monazite	Phosphate	India, Brazil, South Africa, U.S., Australia, Malaya, Canada, Korea, Ceylon, Indonesia
Bastnasite	Fluocarbonate	U.S. (California)
<i>Yttria Group (Heavy Rare Earths)</i>		
Gadolinite	Silicate	U.S., Scandinavia, Germany, Ireland, Austria, Italy, Ceylon, Greenland
Xenotime	Phosphate	Scandinavia, Switzerland, Brazil, U.S.
Euxenite	Columbate	Scandinavia, Madagascar, Brazil, Greenland, U.S., Canada, Australia
Samarakite	Tantalate and uranate	U.S., U.S.S.R., Canada, Madagascar, West Africa

Geochemical processes tend to concentrate in a given mineral the rare-earth ions of closely similar radii. The light rare earths (lanthanum to europium) usually occur together in a group of ores, rich in cerium, called the ceria group. Another group of ores, called the yttria group, contains the heavy rare earths and yttrium. However, varying amounts of all the rare earths (except promethium) are found in each known rare-earth mineral.

Some of the rare earths are found among the fission products of thorium, uranium, and plutonium; a number of new radioactive isotopes have been obtained from such sources. In addition, a considerable number of radioactive isotopes of the rare earths have been produced artificially. (See RADIOACTIVITY.)

Recovery and Separation.—The rare-earth ores are usually concentrated by mechanical methods. Then, depending on the type of ore, they are leached by hydrochloric or sulfuric acid, or else fused with sodium carbonate, sodium hydroxide, sodium hydrogen sulfate, or potassium hydrogen fluoride. The rare earths in the resulting solutions are next separated from gross amounts of other elements (e.g., iron, aluminum, and silicon) by various precipitation processes using such anions as hydroxide, fluoride, phosphate, oxalate, and double alkali sulfate. In some cases the rare earths are separated into the ceria fraction and the yttria fraction; these fractions contain the rare earths in the same proportions as in the original ore.

Because of the great chemical similarity of the rare earths,

separation of the individual elements is difficult. Until other processes were developed during World War II and the decade following, rare earths were for the most part separated by the laborious procedures of fractional crystallization, precipitation, and fractional thermal decomposition. Due to the inordinate amount of time and effort required, only limited amounts of the scarcer rare earths were separated as pure fractions. The occurrence of rare earths in fission products stimulated greater research efforts, resulting in the development of ion-exchange and solvent-extraction techniques. The classical fractional separation techniques are now only of historical importance but were essential to the discovery of the rare-earth elements and in preparing pure samples for determination of chemical properties, atomic weights, and other physical properties.

Separation based on oxidation states other than 3+ has been used with some success, for a change in valence causes a rather drastic change in properties. Cerium, praseodymium, and terbium are the only rare earths that can exist in the four-valent state; of these, only cerium (IV) is stable in water solution. It is much less basic than the trivalent rare earths and its salts are less soluble in basic aqueous solutions. It is commercially separated from the trivalent ions of the group by precipitation, crystallization, and extraction. Quadrivalent praseodymium and terbium are powerful oxidizing agents and, as they are reduced to the trivalent state by water, cannot exist in aqueous solution. Some separations have been effected with fused salts and alkalis. Samarium, europium, and ytterbium can be reduced to the divalent state; of these, europium is the only one separated by this means: the trivalent ion is reduced by zinc and coprecipitated with barium as sulfate.

Chemical techniques employing ion-exchange resins (see ION EXCHANGE) have been used with great success for separating large quantities of pure rare-earth elements. Synthetic organic resins containing a number of active exchange sites have been developed and are used in this process. The scheme developed by F. H. Spedding and J. E. Powell and used for commercial production is as follows: A vertical tube with a porous plug and valve at its base is filled with an ion-exchange resin which exchanges only cations. A weakly acidic rare-earth solution, from which impurities have been removed by conventional chemical techniques, is poured onto the top of the column and allowed to flow slowly through. Because of their high electrical charges, the trivalent rare-earth ions replace the hydrogen ions on the resin and are held near the top of the column, the hydrogen ions going into solution. A solution of an eluting agent such as ethylenediaminetetraacetic acid (EDTA) is slowly passed through the column from the top, forming complexes (chelates) with the rare-earth ions. Due to differences among the equilibrium constants of the rare earth-EDTA complexes, the rare-earth ions move at different rates down the column and are thus separated into bands. At the bottom of the column, separate fractions of the solutions, each containing an individual rare earth, may be removed. The flow of liquid through the column must be sufficiently slow so that equilibrium is maintained throughout the process in order to achieve maximum separation. The control of acidity is also important since the equilibrium constants change with the pH.

Solvent extraction, a low-cost method which lends itself to continuous operation requiring little attention, also has been used for large-scale separation. Kilogram quantities of some rare earths, of high purity, have been prepared by this method, using tributyl phosphate in contact with rare-earth nitrate solutions in a countercurrent extractor. Among other solvents in use are di(2-ethylhexyl) phosphoric acid, monoalkyl phosphoric acids, and certain ketones, esters, and alcohols. Other purification methods used for certain rare earths are electrolytic reduction, or reduction by the use of sodium amalgam, in either case to form amalgams.

Properties of Ions and Compounds.—*Magnetism.*—The magnetic behaviour of the rare-earth ions is of theoretical interest. Trivalent lanthanum, with a xenon electronic structure and no unpaired electrons, is diamagnetic; for the same reason trivalent lutetium (fourteen 4f electrons), divalent ytterbium (fourteen

4f electrons), and tetravalent cerium (no 4f electrons) also are diamagnetic. All other ions of the rare earths are paramagnetic. The paramagnetism of the trivalent rare-earth ions increases somewhat irregularly from cerium to a maximum at dysprosium and holmium and then decreases to zero at lutetium. The magnetic character of an atom or ion is due primarily to the forces associated respectively with the spinning motion and the orbital motion of its electrons. If the electrons are all paired the magnetic effects are nullified and the substance is diamagnetic; if unpaired electrons are present the substance is paramagnetic. It might seem that the gadolinium (III) ion, with the maximum number of unpaired electrons (seven), should have the greatest paramagnetism; instead, dysprosium and holmium have the highest shown by any of the elements. This variation has been quantitatively explained by J. H. Van Vleck on a theoretical basis: it is thought that the paramagnetism of gadolinium is due only to the spin effects of the seven unpaired electrons, whereas in the other cases the observed values are due to a combination of spin and orbital effects. (See also **MAGNETISM: Paramagnetism: Rare Earths.**)

Spectroscopy.—Certain trivalent rare-earth ions exhibit extremely sharp, narrow absorption peaks in the ultraviolet, visible, and near-infrared regions of the spectrum. These lines are due to the transfer of electrons within the 4f subshell, with resulting absorption of the light waves of that particular energy. This characteristic sharpness was unique with the rare-earth elements until the actinide elements, particularly americium, were synthesized (see **TRANSURANUM ELEMENTS**). The actinides contain electrons in the 5f subshell and have similarly sharp absorption lines. These absorptions are of interest in determining electronic structures and of practical use for quantitative analysis.

Valency.—The common and characteristic oxidation state of the rare earths is 3^+ . In addition, cerium, praseodymium, and terbium are also tetrapositive; and samarium, europium, and ytterbium are dipositive. The explanation for the non-tripositive valences is found in the unusual stability of empty, half-filled, and filled electron subshells. The trivalent ions of lanthanum (no 4f electrons), gadolinium (seven 4f electrons), and lutetium (fourteen 4f electrons) are examples. The neighbouring elements tend toward more stable configurations: cerium and praseodymium each lose an extra electron to form tetravalent compounds and to achieve the lanthanum or near-lanthanum 4f structures; terbium loses an electron to become tetravalent, while samarium and europium each gain an electron to form divalent compounds—all three tending toward the gadolinium structure; and ytterbium gains an electron to become lutetium-like in the divalent state.

Fusion of a trivalent rare-earth halide with its own metal in a sealed tantalum container has resulted in the preparation of compounds of lanthanum, cerium, praseodymium, and neodymium in which the apparent valence of the rare earth is below three. Neodymium forms a true 2^+ ionic salt; the other three a "metallic" bonded compound having high electrical conductivity. Thulium has been prepared also in the divalent state by treatment of the metal with iodine vapour; the TmI_2 prepared is a true ionic salt. Both Nd^{+2} and Tm^{+2} are very strong reducing agents and are not stable in aqueous solution.

The properties of the rare-earth trivalent ions are much the same, changing primarily in degree from the lightest, lanthanum, to the heaviest, lutetium. The trivalent nitrates, chlorides, bromides, iodides, perchlorates, and sulfates are all very soluble in water. The fluorides, oxalates, phosphates, double alkali sulfates, and hydroxides are the more insoluble compounds, much used in the older separation methods. The rare-earth ions do not form stable complexes with most inorganic ions but do form complexes of varying stabilities with a number of organic chelating agents. The basicity of the ions decreases from lanthanum to lutetium, which is quite weak.

The Metals.—All of the rare-earth metals except promethium have been prepared in very pure form and some of their properties have been determined (see **METAL**, table). Because of the high reactivity of the metals they cannot be prepared from water solutions of their salts by either electrolytic or chemical reduction. They are produced by electrolysis of molten salts or by chemical

reduction of the dry halides with alkali or alkaline-earth metals. Reduction of the oxides by alkaline-earth metals or even by a less volatile rare-earth metal, followed by distillation of the pure rare-earth metal, is another method; e.g., the oxides of samarium, europium, and ytterbium may be reduced in a vacuum by lanthanum and the liberated metal purified by distillation.

The rare-earth metals are of silvery lustre. The lighter members of the group are quite soft and the heavier metals are much harder. They are, in general, strong reducing agents and are extremely reactive. The metals tarnish in air; in powder form they ignite spontaneously. They react with hot water, liberating hydrogen. Although in aqueous solution the ions and compounds of the rare earths are quite similar, the metals show marked differences in physical properties. The differences in melting points of the various metals vary as much as 800°C . There are similar wide differences in volatility; e.g., at a given temperature europium is many times more volatile than lanthanum.

RASH: see **SKIN, DISEASES OF.**

RASHI (RABBI SOLOMON [SHELOMOH] BEN ISAAC) (1040–1105), Jewish scholar, commentator par excellence, author of the great and supremely popular commentaries on the Bible and the Talmud, was born at Troyes, France. The name Rashi was derived from the initial letters of his full name. He was a member of a cultured family and a blood relative of the greatest scholars of Germany of the second half of the 11th century. Two personal misfortunes determined his life's work. His father Isaac died when Rashi was a child, and his mother was left with a large vineyard as the sole source of the family income. He was thus denied his burning ambitions: to be a perpetual student and to spend his life in Mainz or Worms, the great centres of talmudic scholarship.

Since he was allowed but a few years to study under Rabbi Jacob ben Yaqar and Rabbi Isaac ha-Levi in Worms, and under Rabbi Isaac ben Judah in Mainz, Rashi had to pursue his studies under great pressure. He did not have the time or the leisure to follow the normal practice of committing to memory the oral explanations of his teachers for every phrase and every statement of the Talmud, and was thus forced to write them down. Upon his return home, the cares and preoccupations of a vintner kept him from the company of scholars and students, and he was thus required to review his notes in private and to attain mastery of talmudic lore through the written word. This master teacher was denied the audience of a large group of eager and enthusiastic pupils and had to direct all his pedagogical instincts and compulsions to unseen students, the perusers of the written word.

BY COURTESY OF THE JEWISH MUSEUM, HEBREW UNION COLLEGE—JEWISH INSTITUTE OF RELIGION
RASHI'S CHAIR, IN NICHE, IN THE STUDY OF THE WORMS SYNAGOGUE

Thus came into being his great written commentaries on the Bible and on the Talmud.

When in 1096 the centres of rabbinic learning in the Rhineland were destroyed by the ravages of the First Crusade, and the great teachers were killed, the commentaries of Rashi were eagerly sought after by hundreds of surviving students-without-teachers. He attracted many students to Troyes, and his school became the most important centre of rabbinic learning in central Europe, a fountainhead of rabbinic scholarship and a concentration point of spiritual leadership for Ashkenazic Jewry. He changed the pattern of rabbinic learning, and caused his students and followers to make use of the pen and to produce a voluminous literature in their effort to complete the process of committing to writing the rich oral traditions of the great schools of German and French Jewry, traditions that had been transmitted orally from teacher to student for a thousand years and were now in danger of disappearance.

Rashi's learning and character raised him to a position of high respect among the Jewries of Europe. His commentaries soon spread even to Spain, and they were respected in the schools of Egypt and of the East. As was said of him soon after his death (at Troyes, on July 13, 1105), "His lips were the seat of wisdom, and thanks to him the Law, which he examined and interpreted, has come to life again."

The most significant members of Rashi's school were members of his immediate family. He had three daughters but no sons, and two of his most important students were his sons-in-law, Rabbi Judah ben Nathan, who eventually wrote commentaries on many tractates of the Talmud; and Rabbi Meir ben Samuel, who also wrote such commentaries. The son of the latter, Rabbi Samuel ben Meir, better known as Rashbam, was his grandfather's greatest and most renowned student. An admirer of the beauty, accuracy, and effectiveness of Rashi's commentary on the Talmud, he tried to emulate it, often overzealously. Rashbam also wrote a commentary on the Pentateuch, characterized by a concentration on the obvious meaning of the text, which became very popular in subsequent centuries. Rashbam's brothers, Isaac ben Meir (Ribam) and Jacob ben Meir Tam, also carried on Rashi's work, the latter as one of the greatest of the Tosafists (glossators).

Other outstanding students of Rashi's school were Rabbi Joseph ben Simon Kara, who wrote an important commentary on all the prophetic books, on Job, and on the Five Scrolls; Rabbi Simcha of Vitry, the compiler of *Mahzor Vitry*, a collection of rules, discussions, and comments, mainly regarding the ritual of services of the synagogue on all festive occasions; and Rabbi Shemaiah, a close associate of Rashi, probably the compiler of *Sefer ha-Pardes*, which was one of the first collections and arrangements of ritual law composed by Ashkenazic Jewry.

In the past seven centuries rabbinic scholars throughout the world have studied the Talmud with Rashi's commentary and the additions of the Tosafists of the 12th-13th centuries. Practically every edition of the Talmud contains the text flanked on each page by these two literary masterpieces.

Rashi's commentary on the Pentateuch, in particular, was very popular. It was printed in hundreds of editions and is still to Jews the most beloved of all commentaries on the Mosaic books. More than a hundred supercommentaries have been written on it. Rashi's influence in Christian circles was great, especially because of the use made of his commentary on the Bible by Nicholas (q.v.) of Lyra, who in his turn was one of the main sources of Luther's version. More than 300 *responsa* of Rashi, to the scholars of his day, were preserved; and in his school were composed several customs and collections of rabbinic lore that had a profound influence on the religious customs of the Jews of subsequent generations.

RASHID AL-DIN FADLULLAH (1247-1318), Persian statesman and historian, author of a universal history, *Jami al-tawarikh*, belonged to a Jewish family of Hamadan but was converted to Islam, and as a physician joined the court of the Mongol ruler of Persia, Abaqa-khan (1265-1282). He became vizier to Ghazan-khan in 1298 and served under his successor Uljaytu. Accused by his rivals of having poisoned his sovereign, he was put to death by Uljaytu's son Abu Sa'id.

Rashid al-Din's history covers a vast field even outside the Muslim world. His sources of information for Mongolia and China were high officials of the Mongol empire and the Mongol records, for India a Buddhist from Kashmir, for the popes and emperors a Catholic monk, etc. There are important chapters describing the social and economic conditions of the Islamic countries under Ghazan-khan (1295-1304) and the reforms introduced by this ruler on the advice of the author himself. Rashid al-Din uses a great number of Mongol and Turkish terms but his style is lucid and matter-of-fact.

The important parts of Rashid al-Din's history were published by E. Quatremère (1936), I. M. Berezin (1858-1888), E. Blochet (1911), K. Jahn (1940), Ali-zade (1958), and A. Atesh (1957). The parts on the Mongolian tribes, on Genghis Khan and on Ghazan-khan, appeared in a new Russian translation (1946-52). Rashid's interesting correspondence with his sons and dependents was published by M. Shafi (1947). (V. F. M.)

RASHT (RESHT), a city and capital of the *ostan* (province) of Gilan in Iran, lies on a left-bank branch (Siah Rud) of the Safid Rud, where the higher ground merges into the marshlands fringing the Mordab or Pahlavi Lagoon, 150 mi. NW of Teheran. Population (1956 census) 109,491; 1962 est. 130,000; in 1940 it had been 121,625. Rasht is mentioned in the 14th century as a place of considerable size, producing silk and cotton. Its importance as capital of Gilan dates from the southward expansion of Russia in the 17th century. It suffered a good deal during World Wars I and II from occupation by the Russian Army, and afterward from the decline of the northern trade. In World War II Rasht was a stage on the Allied supply route to the U.S.S.R.

The city is surrounded by rice fields and areas of half-cleared jungle. The summer climate is damp with an annual average temperature of 66° F (19° C) and a rainfall of 32-59 in. It was heavily infested by malaria until after World War II. The houses are mostly of handsome though soft red brick, two-storied, and with much woodwork such as broad verandas and overhanging eaves. The roofs are red-tiled in contrast to the steep thatched roofs of the countryside, and the houses are often raised from the ground. Most of the old streets are still paved with cobblestones. Modernization is confined to the main streets and thoroughfares.

Rasht is an important regional centre, marketing most of the agricultural surpluses of Gilan, especially rice, also tea, groundnuts (peanuts) and other cash crops, and silk. It is an administrative and cultural centre with many public services. The bazaar is large and lively, with many crafts. Local agricultural products (rice, tobacco, silk, kenaf) are processed; soap, glass, and razor blades are also manufactured. The largest plant is a mill for kenaf (jute) bags. Modern developments have been slow. In 1962 a large dam on the Safid Rud, designed for improving irrigation on the Gilan Plain and for electric power, was completed. An extension to Rasht of the oil pipeline from the main line in Teheran was under construction.

Rasht is connected by good roads with the port of Pahlavi and, via Kazvin, with Teheran and the rest of the highland. It is also linked through Lahijan with the *ostan* of Mazandaran and through Astara on the Soviet frontier with Tabriz. There is an airfield to the north of the town. (H. Bo.)

RASHTRAKUTA (RATT), the name of an Indian dynasty that ruled over the Deccan (q.v.) and neighbouring lands from A.D. 757 to 975. A royal family of Lattalur (Latur near Osmanabad), with branches as far north as the Tapti and farther south at Saundatti (40 mi. ESE of Belgaum), they were at one time leading feudatories of the Chalukya (q.v.) dynasty of Vatapi. They spoke Kanarese, but knew the northern Deccan. They ousted the Chalukyas of Gujarat and the Sendrakas and struggled constantly with the Chalukyas of Vengi.

Under their leadership the Deccan became the second greatest

political unit of India. The emperor at Malkhed (near Gulbarga) was called the Sri-Prithvi-Vallabha (the "Ballaha-ra" of Arabic authors). Krishna I acquired the Konkan and built the famous Kailasa, the rockcut temple at Ellora. Dhruva subdued the Gangas of Gangavadi (Mysore), contained the Pallava (q.v.) of Kanchi (Kancheepuram), and defeated the king of Bengal and the Pratihara king, who were contending for Kannauj. Amoghavarsha reigned from 814 to 878, during which time the Gujarat branch of the family and Vengi shook themselves free. He was of a contemplative character, and the author *inter alia* of the *Kavirajamarga*, the earliest-known Kanarese poem. Krishna II, who succeeded in 878, reacquired Gujarat but failed to retake Vengi. His grandson Indra III came to the throne in 914. He took Kannauj and brought Rashtrakuta power to its peak. Krishna III outdid him in northern campaigns (c. 940) and in a spectacular occupation of Kanchi and much of the Tamil Plains (948–966/67). Khottiga Amoghavarsha IV (968–972) failed to protect the capital from the Paramara, and its sack destroyed faith in the dynasty. The emperor fled to the Western Ghats, where his line lingered ignominiously, supported by brave Ganga and Kadamba feudatories, until Taila Chalukya won the succession c. A.D. 975.

(J. D. M. D.)

RASIN, ALOIS (1867–1923), Czech patriot, one of the founders of Czechoslovakia and its first minister of finance, was born at Nechanice, in Bohemia, on Oct. 18, 1867, and studied law in Prague. In 1893 he was arrested in connection with the Czech patriotic *Omladina* conspiracy against the Austrian authorities and sent to prison. Amnestied in 1895, he then worked as a lawyer in Prague. At first he joined the Young Czech Party led by Karel Kramar, then in 1899 he founded a new Radical-Progressive Party, and later he was reconciled with Kramar. In 1911 he was elected to the Austrian parliament (*Reichsrat*) as a Young Czech. His activities before World War I were extensive. In his contributions to the Czech newspaper *Narodni Listy* and elsewhere he expressed a particular interest in social and medical questions.

Arrested as a traitor to Austria in July 1915, Rasin was condemned to death on June 3, 1916; but the sentence was later commuted, and in June 1917, after the accession of the new emperor, Charles I, he was amnestied. He was thus freed in time to become a leading member of the new Czechoslovak National Council, which organized the Czech take-over of power in Prague in October 1918. When the republic of Czechoslovakia came into being, Rasin, now a National Democrat deputy, was its first minister of finance and showed great efficiency in the establishment of a balanced budget and the new Czechoslovak currency. Shot by a young revolutionary named Soupal in January 1923, he died of his injuries on Feb. 18, in Prague. His *Financial Policy of Czechoslovakia During the First Year of Its History* appeared in English in 1923.

(E. Wl.)

RASK, RASMUS CHRISTIAN (1787–1832), Danish philologist, a founder of the science of comparative linguistics, was born at Brändekilde, Fünen, on Nov. 22, 1787. He studied at Copenhagen, and was appointed assistant keeper of the university library in 1808 and later professor of literary history. Rask was one of the first to recognize that the Celtic languages are Indo-European; he anticipated Jacob Grimm in the formulation of the first Germanic consonant shift, and Ferdinand de Saussure in his realization of the function and character of minimal speech sounds (the phoneme). He wrote grammars of Icelandic, Old Norse, Old English, Spanish, Frisian, and Italian; treatises on Jewish and on Egyptian chronology; edited parts of the *Edda*; and published innumerable papers on linguistic and literary topics. He also brought out the Icelandic Lexicon (1814) of Björn Haldorson.

Rask was the first president of the Icelandic Literary Society; but in 1816 he left Denmark to prosecute inquiries into the languages of the east and collect manuscripts for the university library at Copenhagen. From Stockholm he went to St. Petersburg, thence through Tatar into Persia, and resided for some time at Tabriz, Teheran, Persepolis, and Shiraz. From Persia he went to India and Ceylon. Rask returned to Copenhagen in May

1823, bringing a considerable number of Oriental manuscripts, Persian, Zend, Pali, Sinhalese, and others, with which he enriched the collections of the Danish capital. He died at Copenhagen on Nov. 14, 1832.

BIBLIOGRAPHY.—See his collected essays, *Samlade Afhandlingar*, 3 vol. (1834–38); selected essays, *Udvalgte Afhandlingar*, ed. by L. Hjelmslev (1932); Otto Jespersen, *Rasmus Rask i hundredåret efter hans Hovedværk* (1918).

RASKOLNIKI; see OLD BELIEVERS.

RASMUSSEN, KNUD JOHAN VICTOR (1879–1933), Danish polar explorer and ethnologist who possessed an unsurpassed ability to win the confidence and understand the character of the Eskimo, was born at Jakobshavn, Greenland, on June 7, 1879. His maternal grandmother was a Greenlander (i.e., of mixed race), and he acquired a thorough mastery of the Eskimo language. After studies at Copenhagen university and a visit to Lapland (1901), he accompanied L. Mylius-Erichsen to northwest Greenland in 1902–04, where he wintered with the most northerly Eskimo tribe in the world (the Polar Eskimo). He was in west Greenland in 1905 to study the possibilities of introducing reindeer husbandry, but spent the next two years with the Polar Eskimo, and in 1910 established, with the aid of privately contributed means, the permanent station at Thule. The object was to provide a trading centre for the population, a base for expeditions and a foundation for the raising of the Polar Eskimo's spiritual, cultural and material level. In 1912 Rasmussen led the first Thule expedition. With three companions he traveled with dog sledges across the Greenland ice sheet from Thule to the northeast coast and back, making valuable geographical discoveries. The second Thule expedition (1916–18) surveyed the north coast of Greenland under very hard conditions. Rasmussen did not personally accompany the third Thule expedition; the fourth (1919) was his journey to Angmagssalik in east Greenland to collect Eskimo tales. The fifth Thule expedition (1921–24) was Rasmussen's greatest. After investigations in northeast Canada, Rasmussen, with two Eskimos, accomplished the longest dog-sledge journey ever made, across the American arctic. He left Danish Island on March 11, 1923, and reached Point Barrow on May 23, 1924. He made a scientific study of every Eskimo tribe, tracing their migration routes and showing the basic unity of their cultures. The sixth and seventh Thule expeditions made cartographic, archaeological and ethnographical studies in south-east Greenland. He died on Dec. 21, 1933, in Gentofte, Denmark.

A brilliant expedition leader, Rasmussen inspired an extraordinary devotion in his companions. Probably no polar explorer has so much used the services of the Eskimo, while he was himself a superb dog-sledge driver. His rich literary production embraces travel descriptions and translations of Eskimo mythology and songs, as well as strictly scientific works, including *Grønland Langs Polhavet* (1919; Eng. trans. *Greenland by the Polar Sea*, 1921) and *Across Arctic America* (1927).

(P. A. B. G.)

RASPBERRY (genus *Rubus*), an old and well-known fruit-bearing bush, mentioned by Pliny as a wild fruit. John Parkinson (*Paradisus*, 1629) speaks of red, white and thornless varieties of raspberries, and their culture began about this time. Raspberry bushes bear juicy red or black (rarely orange, amber or pale yellow) berries which separate from the core that remains on the plant; in blackberries, the core is a part of the fruit.

Distribution.—The raspberry section of *Rubus* probably evolved in eastern Asia, where there are more than 200 species known. In Great Britain and throughout Europe only one species, *R. idaeus*, is known, from which the European cultivated varieties are derived. In the United States and Canada, three species (*R. strigosus*, the red raspberry; *R. occidentalis*, the eastern black raspberry; and *R. leucodermis*, the western black raspberry) are found. American red varieties are derived from *R. strigosus* and hybrids of it with *R. idaeus*. They are much hardier and less prickly than European varieties. Black varieties came from *R. occidentalis*; purple varieties are hybrids of the black and red. Related edible berries, often called raspberries, are the two flowering raspberries of northern American woodlands, *Rubus odoratus* and *R. parviflorus*; the Rocky mountain flowering raspberry, *R.*

deliciosus; and the salmonberry, *R. spectabilis*, of the Pacific northwest. Three other raspberries are grown for their fruit in other parts of the world—the Andes black raspberry, *R. glaucus*, in northern South America and Central America; the southern Asian black raspberry, *R. niveus*; and the wineberry, *R. phoenicolasius*, introduced from northeastern Asia. *R. kuntzeanus* from China has been hybridized with the Cuthbert to give the Van Fleet, and *R. biflorus*, also from China, has been hybridized with Latham to give the Dixie, both adapted to the southern U.S.

ROCHE
BLACK RASPBERRIES (*RUBUS OCCIDENTALIS*)

Acreage and Varieties.—In Great Britain about 10,000 ac. of red raspberries are cultivated. The Blairgowrie district is the centre of production in Scotland; Kent, the eastern counties and Worcestershire are centres in England. Raspberries are sometimes grown in mixed plantings with other fruit, the plants being set at 18-in. intervals in rows 6 or 7 ft. apart. Lloyd George is a leading variety, with large berries good for canning and jam. Red Cross, Pynes Royal and Malling Promise are other good varieties.

The acreage of raspberries in the United States is about 20,000. Black raspberries are nearly as important as red; the acreage of purple varieties is small. Important raspberry sections are western Maryland, southern New Jersey, the Hudson river valley, western New York, western Michigan, near Minneapolis, Minn., the Puyallup valley of Washington, and the Willamette valley of Oregon. Few plantings in the United States, except in the Hudson river valley, are mixed with other fruits. Good red varieties are Willamette, Canby and Washington, in the Pacific northwest; Sunrise, for early, and Latham, for late, for eastern states; and Taylor and Milton, in New York and New England. Cumberland is the chief black variety. In eastern Canada, Viking and Newman red varieties are widely grown. Sodus and Marion are desirable purple varieties. September and Durham are red sorts that also bear fruit on the young canes in late summer and fall.

Propagation.—Red raspberries are propagated by suckers from the roots of the parent plant. Root cuttings about three inches long are also used for rapid increase of new varieties. Black and purple varieties have arched canes and are propagated by tip layers, the tips of the shoots being buried about two inches deep in August and the rooted tips being dug in early spring. Leaf-bud cuttings may be used for the rapid propagation of new black varieties. Red raspberries are usually planted 2½ ft. apart, the black and purple about 4 ft. apart in rows 6 to 9 ft. distant. Shoots are produced in spring and summer that bear fruit the following year and then die. These old canes are cut away each year just after the harvest to make room for the new shoots. The new shoots of the black varieties are tipped or cut off at 12 in. to induce branching; those of the purple at 18 to 24 in. The branches are shortened the following winter to about 8 in. for the black and 12 in. for the purple. The canes of the red raspberries are either not pruned or are shortened to 3 to 5½ ft., depending on the variety and vigour. However, surplus suckers should be cut away early in the summer, leaving seven or eight of the strongest canes per plant or per 30 in. of row. The stouter the canes of both black and red varieties, the more productive they are. Stakes or trellises are commonly used to support the canes of the red raspberry. Two-wire trellises with a wire on each side of the row about 3 ft. high or with one wire above the other at 30 in. and 54 in. are common.

Virus diseases, leaf spot, anthracnose, crown gall, wilt and orange rust are serious diseases, while the red spider mite, crown borer and fruit worms are serious insect pests.

See U.S. Department of Agriculture *Farmers' Bulletin* 887 (1948). (G. M. D.)

RASPE, RUDOLF ERICH (1737–1794), German scholar and adventurer, the original author of the *Adventures of Baron Munchausen* (see MUNCHAUSEN), was born at Hanover in 1737 and studied natural sciences and philology at Göttingen and Leipzig. He worked in university libraries and was appointed librarian and custodian of the Landgraf's collection of gems and coins at Kassel in 1767. He won a scholarly reputation with learned articles on many subjects (he was one of the first to interest himself in Ossian and in Percy's *Reliques*) and was elected a fellow of the Royal Society in 1769; but in 1775 he began stealing from the Landgraf's gem collection and finally had to flee to England to escape arrest. Here he lived on his wits, at times near starvation, and *Munchausen*, published anonymously, was produced during this period (1785). In 1791 he was involved in a swindle concerned with mining in Scotland, and fled to Ireland, where he died of fever at Muckcross, County Kerry, in 1794. His authorship of *Munchausen* was only revealed in 1847 by Heinrich Döring in his biography of G. A. Bürger, who had translated the book into German.

See R. Halls, *Raspe* (1934); J. P. Carswell, *The Prospector, Being the Life and Times of Rudolf Erich Raspe* (1950). (W. D. W.)

RASPUTIN, GRIGORI EFIMOVICH (1872?–1916), Russian peasant and mystic who became a powerful favourite at the court of the emperor Nicholas II, was born at Pokrovskoe, near

CULVER PICTURES INC.

GRIGORI EFIMOVICH RASPUTIN

Tyumen, in western Siberia; his original family name was Novykh. Though he received no formal education, he was extremely astute. He had an extraordinarily magnetic personality and seems to have possessed hypnotic powers. In early manhood he came under the influence of adherents of the sect of the Khlysty ("Flagellants"); he claimed to be divinely inspired and to be able to work miracles. In particular he preached that physical contact with his own person had a healing and purifying effect—a doctrine which served him as a convenient means of gratifying his phenomenal sexual appetite.

He was accused of heresy, but the proceedings against him were dropped. He was already being called Rasputin, meaning "debauchee."

Adopting the role of a holy man (*starets*), Rasputin set out as a pilgrim and, in 1903, arrived in St. Petersburg. There he was befriended by high-ranking Orthodox prelates and attained admission into aristocratic society. Mysticism was the fashion, and Rasputin was soon the centre of a circle of admiring female devotees. In November 1905 he was introduced to the imperial couple. His powers of suggestion had a soothing effect on the tsarevitch Alexis, who suffered from hemophilia, and also on the empress Alexandra (*q.v.*). She came to look on Rasputin as a saint, sent by God to save the dynasty. The emperor Nicholas was less impressed, but readily succumbed to her persuasions. Rasputin urged on the imperial couple the need for firm autocratic government and presented himself as a simple *muzhik*, the voice of the loyal and God-fearing peasantry, whose opinions were more worthy of attention than those of the emperor's high-born advisers.

Though Rasputin behaved at court with relative decorum, elsewhere he indulged in uninhibited licence; and in the course of his debauches he would often boast in exaggerated terms of his intimate relations with the imperial family. His former ecclesiastical protectors denounced him as an impostor, but were themselves arbitrarily punished. When references to Rasputin's influence appeared in print, the offending publications were confiscated. The matter was discussed in the Duma, which led to tension between it and the court. Early in 1912, Rasputin was sent back to his native village. Yet he remained in favour; and by the autumn of 1914, having survived an attempt on his life, he

was once again firmly ensconced in the capital.

World War I had meanwhile broken out, and after Nicholas' assumption of supreme command in the field (September 1915) the empress and Rasputin were left in virtual control of domestic affairs. When appointments were made Rasputin's opinions generally (although not invariably) carried decisive weight. A number of honest and capable ministers and officials were dismissed, being replaced by worthless nonentities or unscrupulous careerists who enjoyed Rasputin's protection. He was surrounded by financial speculators and morally corrupt individuals whose requests for favours he and his placemen endeavoured to satisfy—as well as those of humble and more meritorious petitioners. He continued his riotous way of living, safeguarded by police agents.

Rasputin followed no consistent policy, but was opposed to the war, which threatened to undermine the Romanov dynasty and thus also his own position; also, like very many ordinary Russians he objected to the wasteful sacrifice of human life. There is no evidence that he was a German agent, as was widely believed at the time. But his activities paralyzed the normal workings of the administration and widened the breach between the court and public opinion. Opposition to the favourite was strongest in right-wing circles. A group of extreme conservatives, headed by V. M. Purishkevich and including the grand duke Dimitri Pavlovich and prince F. F. Yusupov, decided to assassinate Rasputin in the hope of saving the monarchy from itself. On the night of Dec. 30–31 (new style; 17–18, old style), 1916, he was done to death in sordid circumstances; after an attempt to poison him, he was shot. The murder merely strengthened Alexandra's resolve to uphold the principle of autocracy, but a few weeks later the whole imperial regime was swept away by revolution.

RAS SHAMRA; see UGARIT.

RAS TANURA (RA'S AT TANNURAH), a port in the Eastern Province (Al Hasa) of Saudi Arabia, lies 25 mi. (40 km.) N of Dhahran. Pop. (1956 est.) 15,000. It is the principal Persian Gulf terminal of the pipelines serving oil tankers from a long jetty built out into deep water and a number of oil tanks are in Ras Tanura. Ad Dammam (see DAMMAM, AD) serves the commercial needs of the kingdom. Ras Tanura is finely situated along the seashore.

(H. Sr. J. B. P.; X.)

RASTELL, JOHN (c. 1475–1536), English lawyer, printer, and dramatist, brother-in-law of Sir Thomas More, was a son of Thomas Rastell, coroner of Coventry. He was educated at the Middle Temple and was himself coroner of Coventry from 1506 to 1509. Before 1504 he married Elizabeth More. Their daughter Joan married the dramatist John Heywood and their second son William Rastell was also a printer. Before 1512 Rastell moved to London. He was in charge of ordnance under Sir Edward Belknap in the French war of 1512 to 1514 and in the campaign of 1523 he was with "the army royal beyond seas" as a trenchmaker. He provided a ship in 1517 for the expedition to colonize Newfoundland, but owing to the mutiny of his mariners he got no farther than Ireland. Rastell decorated the roofs of the banqueting hall erected at the Field of Cloth of Gold (1520). For the reception of the emperor Charles V in 1522 he set up a pageant near his shop at the "little conduit in Cheap," representing heaven with "clouds, orbes, starres and hierarchies of angels"; he presented another pageant, the "Father of Heaven" for the entertainment of French ambassadors at Greenwich in 1527. The stage which Rastell built at his house in Finsbury Fields in about 1525 is the earliest known in London.

Rastell's book *Canones astrologici*, mentioned by John Bale in his *Illustrium majoris Britanniae scriptorum . . . summarium* (1548), has not been traced. He wrote *Elements* (?1517) and perhaps others of the interludes issued from his own press, for whose title page he used an astronomical device. He also printed *The Merry Jestes of the Widow Edith* (1526) by More's servant Walter Smyth, and the *Hundred Merry Tales* (1526), the first of the Tudor jest-books. Other works from his press included his

own abridgment of Robert Fabyan's *Chronicle*, issued as *The Pastyme of the People* (1529), and several important law books, his own *Liber assisarum* (1513), *The Abbreviation of the Statutes* (1519 and frequently reprinted), the *Expositiones terminorum legum Anglorum* (1527 and frequently reprinted), and Anthony Fitzherbert's *Le Graunde Abridgement* (1516).

Rastell was a member of the Reformation parliament (1529–36). He engaged in controversy against the Lutherans, printing More's *A Dialogue Concerning Heresies and Matters of Religion* (1529) and his own vigorous *A New Booke of Purgatory* (1530), presented in dialogue form, supporting the arguments of More against the reformer John Frith. But Rastell was converted by his brilliant opponent; he dissociated himself from More and followed Thomas Cromwell. His anxiety to abolish all tithes and oblations, however, brought him into disfavour, and he was imprisoned for opposing the Royal Proclamation of 1535 on that subject. He died in prison on June 25, 1536. His life had been much embarrassed by lawsuits. While More was chancellor (1529–32) Rastell's practice was considerable.

Craik, *The Tudor Interlude* (1958); E. G. Duff, H. R. Plomer, and R. Proctor, *Handlists of English Printers 1501–1556*, vol. ii (1896). (H. W. Do.)

RASTELL, WILLIAM (1508–1565), English lawyer and printer, nephew and biographer of Sir Thomas More, whose works he preserved and printed, was a son of John Rastell and Elizabeth More. Educated in his father's office as scribe and printer, he set up his own press in 1529 and printed More's controversial writings, John Heywood's interludes, and *The Legacye or Embassate of Prester John unto Emanuell, Kyng of Portingale*, John More's translation of the work by Damião de Goes. For law students he printed 12 of the principal legal textbooks in one volume, *Natura brevium* (1533–34). Rastell was admitted to Lincoln's Inn in 1532 and was called to the bar in 1539; he was pensioner of the Inn in 1545, reader in 1546, keeper of the Black Book (the Inn's register) from 1548 to 1549, when he became treasurer. In that year the use of the first prayer book of Edward VI was enjoined, and Rastell went into exile with his wife, Winifred, daughter of More's pupil John Clement and Margaret Giggs, More's adopted daughter. They settled at Louvain, where Winifred died in July 1553. During his exile Rastell preserved More's writings and after his return following the accession of Queen Mary (July 1558), he had the *English Works* printed by Richard Tottel. In this period of his life Rastell also published important law books of his own, *A Collecion of All the Statutes* (1559) and *A Collecion of Entrees* (1566). Of his large biography of More only a fragment survives. He became sergeant-at-law in 1555 and benchler of Lincoln's Inn in 1558. Early in 1563 he went into exile again and died on Aug. 27, 1565, at Louvain, where he was buried with his wife.

BIBLIOGRAPHY.—The fragments of Rastell's biography of More are printed with Nicholas Harpsfield's *Life and Death of Sir Thomas Moore*, ed. by E. V. Hitchcock (1932) for the Early English Text Society. See also A. W. Reed, *Early Tudor Drama* (1926) and Introduction in *The English Works of Sir Thomas More*, ed. by W. E. Campbell (1931); R. W. Chambers, *Thomas More* (1935).

(H. W. Do.)

RAT, a term applied indiscriminately to many rodents; more specifically, to the many species of the genus *Rattus* (family Muridae), the most varied genus of mammals, containing more than 500 named forms. Ordinarily, however, the term denotes either the "domestic" Norway—brown, barn, sewer, or wharf—rat, *Rattus norvegicus*, or the roof—black, gray, climbing, or Alexandrine—rat, *R. rattus*. Both were originally Old World species but have become virtually cosmopolitan through the agency of man. Norway rats are usually brown, but gray, white, black, and pied specimens are not infrequent. They are larger (seven to ten inches, not including the tail) and more robust than roof rats (up to eight inches long); their tails are shorter than the combined head and body length; the ears are small and half buried in the fur. Roof rats also vary in colour, certain colour phases tending to predominate regionally, but the commonest is dark gray. Their tails are longer than the head and body; the ears are large and

erect and project well beyond the fur.

Originally the Norway rat occurred in cooler areas; the roof rat, in warmer areas. Thus, although the species are widespread and strongly competitive, their relative frequency is partly dependent upon climate. In the United States, for example, roof rats occur mainly in the southeastern states. Generally the Norway rats, being larger and more adaptable, vanquish roof rats, and when both occur in an area they occupy different habitats. If both occur in a building, for example, it would be a light infestation, the Norway rats occupying the lower levels and the roof rats, the upper floors.

Rats are aggressive, active, omnivorous, adaptable, and fecund—immensely successful as biological organisms. They have been known to destroy poultry, game, crops, and stored grain. Adults are fertile at all seasons. In warm places litters are produced at about two-month intervals; in cooler places, at about four-month intervals. Gestation is 20–25 days. The 6 to 22 helpless, naked young are born in a secluded site. They are weaned in a month and are ready to breed in three to four months. Rats have acutely developed senses, especially of touch and hearing, as befits essentially nocturnal animals. They climb with surpassing ease; this skill, coupled with an ability to jump and a propensity to burrow and gnaw, gains them entry to places inaccessible to many other small mammals.

When driven by hunger, thirst, or foul weather, they are resourceful and unrelenting in their attempts to enter buildings, yet ratproof construction and adequate sanitation are the best methods of control. Rats are prone to burrow along a building foundation sometimes for great distances attempting to gain entry. If deflected away from the foundations, however, by a structure such as a curtain wall, they desist. Rats may also be controlled by a coordinated and vigorously prosecuted program of trapping, poisoning, and fumigation. Because of their exceedingly destructive habits, rats are of enormous economic importance, causing millions of dollars in damage annually in the United States alone. They are also of importance in public health, having been implicated in harbouring or in transmitting directly or indirectly more than 20 diseases, including typhus fever, plague, rat-bite fever (sodoku), hemorrhagic jaundice, tularemia, rabies, trichinosis, and salmonellosis. The common laboratory white rat, a domesticated albino strain of the Norway rat, is an invaluable experimental animal in biological and medical research.

Several other families of rodents have members called rats. The Cricetidae include the cotton rats (*Sigmodon*), rough-coated rodents that are ranch and farm pests in the southern U.S., Central America, and parts of South America; rice rats (*Oryzomys*), with much the same distribution; and pack, wood, trade, mountain, or brush rats (*Neotoma*), of North and Central America, noted for their habit of collecting small, shiny objects. The family Rhizomyidae comprises the bamboo or root rats of Asia. Among the Heteromyidae are the kangaroo rats (*Dipodomys*) of southwestern North America, with stiltlike hind legs used for leaping. See also **RODENT**; and references under "Rat" in the Index.

RATCHET AND PAWL is an important mechanical device in many machines and appliances, enabling a movement to be effected in one direction but not in the opposite direction. The mechanism is used to lock a part so that it cannot slip or reverse, to hold a load as in a winch or to give a positive feed. Ratchets may be straight or curved, the majority being circular. In fig. 1, motion of the arm (B) in the direction of the arrow rotates the wheel (A). When the arm (B)

Counterclockwise rotation of inner driving member turns outer driven member by wedging action of balls: (A) basic single-ball mechanism; (B) basic type with springs to insure positive wedging in any starting position; (C) multiple-ball type with lining protecting driven member

reverses, supplementary pawl (D) prevents backward motion of the wheel, providing the typical intermittent motion in one direction for the wheel.

Slack in the engagement of the teeth may be reduced by using smaller teeth, additional stationary pawls or by using the silent (free-wheeling) ratchet (fig. 2). A variety of constructions employ balls, rollers or eccentrically pivoted pawls to wedge in tapered slots and provide silent, smooth, slack-free motion in one direction.

Various drives and brake mechanisms are made safe by ratchet devices, the ship's capstan being one of the oldest examples. Screwdrivers and wrenches are operated by ratchet for access in difficult situations, or to help the worker in manipulative power. Braces and metal drills are actuated by ratchets when it is not possible to make the complete revolution of a handle. So also are jack screws actuated for lifting loads rapidly. Many counting devices are based on the use of ratchets. Ratchet feed, by which an arm holding the pawl is moved, thus moving a ratchet wheel and a feed screw, is utilized in many types of machines and is usually automatic in action. For example, the workpiece table on a shaper may be moved sideways a small space for each stroke of the cutting tool, a movement which will provide a complete traverse of the surface of the piece being machined. (F. J. B.)

RATEL (HONEY BADGER), a short-legged, carnivorous mammal, *Mellivora capensis*, of the weasel family (Mustelidae), about the size and build of the badger (*q.v.*). The tail is short, the ears

PAUL POPPER

RATEL (MELLIVORA CAPENSIS)

rudimentary, and the front claws very large and strong; the upper parts are whitish, but the face, lower parts, and legs are black, the two colours being separated sharply. Several subspecies are recognized, differing in details of colouring.

Rats are found throughout most of India, through the Middle East and Africa to the Cape. They are nocturnal and live in burrows dug with their strong, incurved front claws. They feed upon

small animals and vegetable matter, and dig out bees' nests to eat the honey. They are fearless fighters, sometimes destructive to poultry, but in captivity become tame and playful. The female has four teats—her litter is probably normally fewer than this—but nothing definite is recorded of the breeding habits. See also CARNIVORE.

(L. H. M.)

RATHENAU, WALTHER (1867–1922), German statesman, industrialist and philosophical writer, was born in Berlin on Sept. 29, 1867. His father was Emil Rathenau, who became a pioneer of the modern power industry by acquiring Thomas A. Edison's European patent rights and founding the Allgemeine Elektrizitäts-Gesellschaft. Having completed an academic curriculum in philosophy, physics, chemistry and engineering, Walther Rathenau successively filled responsible positions in various industrial enterprises, and in 1899 entered the service of the Allgemeine Elektrizitäts-Gesellschaft. Although he had always been interested in public affairs, it was not until the beginning of World War I that he became a public figure.

The cause of Rathenau's prominence was the fact that, almost alone among German industrialists, he realized in the early days of the war the dependence of the German war effort on the supply and prudent management of raw materials. His proposal to organize a special board of the war ministry for this purpose was accepted, and he was put in charge, directing this vital work until the spring of 1915. Then he returned to business activity and writing; his best-known book, *Von kommenden Dingen* (1917; Eng. trans. by Eden and Cedar Paul, *In Days to Come*), was produced during this period.

Rathenau's knowledge of the world outside Germany, and his genuine love for peace, co-existed in his mind with strong national feelings. In Oct. 1918, in despair over the German armistice request, which he correctly interpreted as in effect an act of unconditional surrender, he proposed in vain a *levée en masse* of the German people. In his economic views, Rathenau held an intermediate position between capitalism and democratic socialism; after the revolution of 1918, he founded with others the middle-class Democratic party, but he tried to keep that party in a relationship of co-operation with the Social Democrats, despite his critical view of many of the policies of the Social Democrats. In his book *Die neue Wirtschaft*, he supported the idea of industrial self-government with the participation of employees and effective state control rather than universal nationalization.

Rathenau was one of relatively few Germans who combined democratic convictions and a strong belief in international conciliation with economic experience and knowledge of foreign countries. In 1921 Karl Joseph Wirth, who had just formed a cabinet, appointed Rathenau minister of reconstruction, a position involving responsibility for important aspects of reparation policy; later he exchanged this portfolio for that of foreign affairs. As one of his first achievements, Rathenau negotiated an agreement with France on German deliveries in kind for the reconstruction of French war-devastated areas. Rathenau believed that a practicable settlement of the reparations issue could best be obtained as part of a European reconstruction scheme, in which the economic rehabilitation of Russia would have to play a vital role. He induced Lloyd George to make this idea the core of the British proposal at the international conference at Cannes (Jan. 1922). No progress was made, however, either at Cannes or at the subsequent conference of Genoa. To forestall an Allied understanding with Russia at Germany's expense, Wirth decided to conclude a German agreement with the Russians for the mutual cancellation of all claims (the Rapallo treaty) and Rathenau reluctantly agreed. Through the Rapallo treaty, Germany for the first time after its defeat asserted its position as an independent agent in international affairs. The treaty antagonized the Allies; its wisdom has remained a matter of controversy.

Even among the conservatives, some leaders had a great deal of personal admiration for Rathenau, though others attacked him with bitterness. For the extreme nationalists Rathenau was the symbol of everything they hated, especially because he was a Jew. On June 24, 1922, some young nationalist fanatics shot Rathenau to death on his way to his office. His assassination initiated the

disintegration of the Wirth cabinet and the sequence of events that led to the French occupation of the Ruhr.

Rathenau's collected works (5 vol.) were published in 1918. Of his later writings, the most important are: *Die neue Wirtschaft* (1918); *Kritik der dreifachen Revolution* (1919); *Die neue Gesellschaft* (1919, Eng. trans., *The New Society*, 1921).

RATHENOW, a town of East Germany in the *Bezirk* (district) of Potsdam, German Democratic Republic. It lies on the right bank of the Havel about 48 mi. (77 km.) W of Berlin by rail on the Berlin-Hanover line. Pop. (1962 est.) 29,218. Rathenow's principal industry is the manufacture of optical goods; its spectacle lenses and frames, binoculars, and opera glasses are exported throughout the world. On the outskirts are a number of brick kilns. The town was founded in 1295. In a battle in 1675 at nearby Fehrbellin the Swedes were defeated by the Brandenburg-ers. Rathenow was severely damaged by bombing attacks during World War II.

RATINGEN, a town of West Germany in the *Land* (state) of North Rhine-Westphalia, Federal Republic of Germany, lies 5½ mi. (9 km.) NE of Düsseldorf by road. Pop. (1961) 36,020. One of the oldest towns of the *Bergisches Land*, it has a 12th-century Gothic church, a Minorite monastery, the geologically interesting Blauer See (lake), the Bürgerhaus with museum, a moated castle, and well-preserved fortifications. Textiles, paper, pottery, glass, electrical goods, and machinery are manufactured.

RATIOCINATION, a term used in logic and psychology for those processes by which the mind proceeds from general to particular truths. The steps involved in ratiocination may perhaps be most clearly seen in the form of reasoning followed in the syllogism (*q.v.*).

RATIONALISM is that system of philosophical belief which asserts that human reason unaided is competent to attain objective truth. In its basic form it is an epistemological doctrine in which reason is contrasted with sense-experience, which is held to be unnecessary, or even a hindrance, to the attainment of truth. The inspiration of rationalism has always been mathematics, and rationalists have stressed the superiority of the deductive over all other methods in point of certainty. They attach a peculiar value to the capacity to recognize necessary connections between abstract ideas or concepts (*e.g.*, the connection between being a Euclidean triangle and having angles equal to 180°). Euclid's *Elements* presents the ideal to which rationalists hold that all human thinking should conform.

According to the extreme rationalist doctrine all the truths of physical science and even history could in principle be discovered by pure thinking and set forth as the consequences of self-evident premises.

Few rationalists, however, have been so extreme, and we may distinguish in different philosophers different degrees of rationalism. Locke, for example, is a rationalist in the weakest sense, holding that the materials of human knowledge (ideas) are supplied by sense-experience or introspection, but that knowledge consists in seeing necessary connections between them, which is the function of reason (*Essay Concerning Human Understanding*). Most philosophers who are called rationalists have also maintained that the materials of knowledge are derived, not from experience, but from the reason itself; *i.e.*, they are innate ideas.

Ethical rationalism is the application of epistemological rationalism to the field of morals. The primary moral ideas (good, duty) are held to be innate and the first principles of morals (*e.g.*, the Golden Rule) self-evident. It is further claimed that the possession of reason provides an adequate motive for moral conduct. In ethical rationalism, reason is generally contrasted with feeling or moral sense.

Theological rationalism asserts the claims of reason against those of revelation or authority. The fundamental principles of religion are held to be innate or self-evident and revelation unnecessary. Theological rationalism thus stresses the importance of natural as opposed to revealed religion. By an easy extension of meaning, the word "rationalism" then came to signify a skeptical

or antireligious attitude. This is the most common use of the word in the 19th and in the 20th centuries. Rationalism is conceived as the ally of liberalism in the struggle against religious intolerance (see W. E. H. Lecky, *History of the Rise and Influence of the Spirit of Rationalism in Europe*, 2 vol., 1914) or alternatively as the enemy of religion (see J. F. Hurst, *History of Rationalism*, 1865). It thus came to be connected, somewhat paradoxically, with empiricism (*q.v.*), the antithesis of epistemological rationalism.

EPISTEMOLOGICAL RATIONALISM

Epistemological rationalism was first explicitly formulated by Plato. According to him there is a system of eternal necessary truths accessible to the human reason apart from sense-experience (*Republic*, vi and vii) and his theory of learning as recollection, developed in the *Meno* and in the *Phaedo*, is the first form of the doctrine of innate ideas. The typical innate ideas are mathematical concepts such as equality, which, he holds, are not perfectly exemplified in the material world (*Phaedo*).

In later antiquity and in the middle ages, wherever Platonism is influential, we have implicit epistemological rationalism (*e.g.*, in the Neoplatonists, in St. Augustine, in Boëthius and in St. Anselm), but it is subordinated to the dominant ethical and theological interests. Medieval theological rationalism, however, makes one important contribution to epistemological rationalism. This is the ontological argument of St. Anselm, in which he seeks to prove that the existence of God follows from His essence, and thus to provide a connection between the abstract system of innate ideas and the actual world. (See ANSELM, SAINT; THEISM.) When rationalism became self-conscious at the Renaissance, both Kepler and Descartes felt the need for this connection, and both use the idea of God, Descartes deliberately reviving Anselm's ontological argument.

Epistemological rationalism reached its highest development in the 17th century under the double impetus of the revival of Platonism and the development of mathematical physics by Kepler, Copernicus, Galileo and Descartes. The new science rests on the basis of mathematics, and it recognizes as clear and distinct only what can be expressed in mathematical form. All scientific truth is derived from certain axioms and principles which can be comprehended by reason as universal and necessary. Thus, according to Galileo, "Truth is written in the great book of Nature, but only he can read it who can decipher the letters in which it is written." These letters, however, are the terms of mathematics, especially of geometry: the concepts of the straight line, the circle, the sphere, etc. None of these concepts is derived from experience; the mind rather takes them "from itself" in order to apply them to sense-perceptions. In the same way, Kepler considers number and magnitude as innate ideas not drawn from experience but required for the scientific investigation of nature (see E. Casirer, *Das Erkenntnisproblem*, 3rd ed., i, pp. 328 ff., 1922; and E. A. Burt, *Metaphysical Foundations of Modern Physical Science*, ch. ii and iii, 1925).

Descartes enlarges this view by setting forth a system of universal concepts of reason which are obtained by analysis of certain fundamental—logical and mathematical—relationships and which can be applied to all empirical data. These concepts are valid, not only for the actual world, but for all possible worlds, so that, in understanding by means of them every effect from its cause, we can obtain a priori knowledge of the universe as a whole. As instances of such fundamental concepts, Descartes cites primarily the concept of being, then the ideas of number and time and of space, figure and motion.

As physics thus becomes a purely deductive science, epistemological rationalism has to draw, as was said above, on theological rationalism for support. The innate ideas are within the mind, and sense-experience constitutes no proof of the reality of the external world (Descartes, *Meditation I*). We can, therefore, get outside the system of our own ideas only by proving the existence of reality external to us. This demands the idea of a Necessary Being, that is, God. But in order to show the applicability of the system, something must also be known of the nature of God. Descartes

states that He is veracious; *i.e.*, that He will not allow us to be deceived in our clear and distinct thinking. The world is, therefore, constructed on the plan according to which we think. It is the construction of an infinite intellect. The applicability of pure mathematics is assured because nature itself is the product of a divine mathematics: *Cum Deus calculat, fit mundus*.

Leibniz' system may be regarded as the crowning achievement of epistemological rationalism. He attempts to deduce from fundamental laws of logic the basic propositions of his system, which are so repugnant to common sense that only a boundless confidence in the powers of pure reason could recommend them. The universe is said to consist of an infinite number of spiritual substances (monads), each regarding the whole from a distinct point of view and with a specific degree of confusion. The human mind occupies an intermediate position in the hierarchy of monads, its perceptions being clear in comparison with those of animals but still involving a great degree of confusion, of which the spatio-temporal and qualitative appearance of things is the product. This confusion also accounts for the fact that the truths of science and history, although logically necessary, cannot be known a priori by human beings.

The gap between truths of reason and truths of fact remains unbridgeable by the human mind. The aim of human science must, however, be to order knowledge so that it approximates as far as possible to the ideal deductive system (see L. Couturat, *La Logique de Leibniz*, especially ch. vi, 1901; and B. Russell, *A Critical Exposition of the Philosophy of Leibniz*, 2nd ed., 1937).

Leibniz attempted to lay the foundation for this in the grandiose scheme of his *characteristica universalis*, which was to give a catalogue of primary simple ideas together with a method by which all truths, however complex, could be exhibited as combinations of them. This project of Leibniz inspired later development in symbolic logic and investigation of the foundations of mathematics, particularly the work of Gottlob Frege, Giuseppe Peano, Bertrand Russell and A. N. Whitehead, in which it is sought to reduce all mathematics to logic. In the 18th century, however, the immediate outcome of the Leibnizian subordination of empirical to rational knowledge was the philosophy of Christian Wolff (1679–1754), who produced the voluminous system now chiefly remarkable as being the form of rationalism in which Kant was reared. Epistemological rationalism was meanwhile subject to attack from the British empiricists, especially Locke and Hume, who stressed the necessity for empirical data in the acquisition of scientific knowledge.

Immanuel Kant (*q.v.*), aroused by Hume from the "dogmatic slumber" induced by Wolff, attempted to combine rationalism and empiricism into a single system, the "critical philosophy." He adheres, however, to the rationalist position in stressing the importance of the a priori element in knowledge; and the "pure forms of intuition" and the "categories," insofar as they belong to the mind, have something of the nature of innate ideas. But he differs from preceding rationalists in holding that, because of their nature, we cannot know that the pure forms of intuition (space and time) or the categories (cause, substance, etc.) apply to reality as such (the thing-in-itself). In short, according to Kant, rationalism provides a satisfactory basis for science only if we adopt skepticism as regards metaphysics. The a priori truths of reason apply only to things as they appear to us (phenomena), and reason is inadequate to solve the metaphysical problems of God, freedom and immortality (*Kritik der reinen Vernunft*, preface to 2nd ed., 1787). It is Kant who provides the classical refutation of the ontological argument (*op. cit.*, "Dialektik").

Hegelianism, in spite of the slogan "The Real is the Rational and the Rational is the Real," is only apparently a return to rationalism, being opposed to the mathematical method and inspiration which provide the keynote of classical rationalism. In fact it may be said that epistemological rationalism has not survived Hume's devastating criticism (*Treatise of Human Nature*, book i). Even the milder Kantian form was subject to severe criticism in the 20th century by the logical positivists, whose conventionalist theory of a priori truth challenges the basic rationalist claim to insight into objective necessary connection.

But however unacceptable as a complete theory of knowledge, rationalism as an attitude has been and still is an inspiration in science. It is the rationalist spirit which urges us to approach nature as masters rather than as pupils and to construct bold hypotheses and verify them later.

Some eminent 20th-century physicists have even put forward deductive systems entirely in the spirit of Leibniz: for example, A. Eddington in his *Philosophy of Physical Science* (1939) and E. A. Milne in his *Modern Cosmology and the Christian Idea of God* (1952).

ETHICAL RATIONALISM

Ethical rationalism was also first developed by Plato, partly under the inspiration of the Socratic dictum "Virtue is knowledge." In the *Republic* the reasoning element of the human soul both recognizes what is right and good and is itself the spring of action which prompts moral conduct. The Stoics, however, among the philosophers of the ancient world, developed the form of ethical rationalism which was most influential in later times. Although they rejected the theory of innate ideas, they held that there is in every man a spark of the divine reason which is sufficient, properly used, to discover the universally binding rules of conduct. On these rules positive law is properly based. Thus the Stoic doctrine gives rise to the theory of natural law and natural right. It was popularized by Cicero, whose writings were later extremely influential (*De Republica*, iii; *De Legibus*, i).

As did epistemological rationalism, ethical rationalism underwent a considerable revival at the Renaissance, when it also had great influence on political theory. The first clear statement that the rules of conduct discovered by reason are independent of the commands of God was made by Hugo Grotius (*De Jure belli ac pacis*, Prolegomena § 11). Ethical rationalism had a considerable vogue in the 17th and 18th centuries, especially in England, where it was developed by Lord Herbert of Cherbury, by Samuel Clarke, by John Balguy, by William Wollaston and by Richard Price.

The ethical systems of Spinoza and Kant have moreover considerable affinities with rationalism: Spinoza's is even developed in the mathematico-deductive form (*Ethica, ordine geometrico demonstrata*) in close connection with his metaphysics and theory of knowledge, though it depends in fact on certain empirical propositions concerning the nature of man; and Kant holds that the form of the moral law, the categorical imperative, is purely a priori, though it provides not a premiss from which we may deduce our duties but a test that enables us to discern the moral character of any proposed course of action.

The classical criticism of ethical rationalism is to be found in Hume's *Treatise*, books ii and iii. A modified form of rationalism was developed in the 20th century under the name "intuitionism" (W. D. Ross, *Foundations of Ethics*, 1939).

THEOLOGICAL RATIONALISM

The question "Is theological truth discoverable by reason or solely by revelation?" could arise only in the context of religions such as Judaism, Christianity and Islam. The relations between revelation and reason were much debated in the middle ages. E. Gilson (*Reason and Revelation in the Middle Ages*, 1938) distinguishes two positions which may be called rationalist as distinct from the antirationalist view that reason is totally unable to grasp religious truth. The less extreme position is the Augustinian, namely that, once revelation is accepted, its content may be grasped by the intellect; this is adopted by St. Anselm, who sums it up in the phrase *credo ut intelligam*, "I believe in order that I may understand." The complete rationalist position, which makes revelation unnecessary at least for the philosopher, was worked out by Averroes in Moslem Spain and adopted by his Christian followers.

Rationalism in theology developed rapidly after the Reformation. A clear statement of the position is given by Lord Herbert of Cherbury in *De Veritate* and *De Religione gentilium*. Leibniz' introduction to the *Théodicée* shows that the word "rational" had already come into use in this context. The position was further developed in the 18th century by the English deists, by the French

philosophes (e.g. Voltaire and Condorcet) and by the German theologians called rationalists (particularly S. J. Baumgarten and J. S. Semler, who were influenced both by Wolffian rationalism and by biblical criticism). (See ENLIGHTENMENT.)

By the end of the 19th century rationalism had become a frankly antireligious movement, often combined with empiricism and materialism and identified with practically atheistic forms of agnosticism (q.v.): see for example J. McCabe, *Biographical Dictionary of Modern Rationalists* (1920) and *A Rationalist Encyclopaedia* (1948).

See also references under "Rationalism" in the Index.

(M. KE.)

RATIONING, a term of military origin that denotes procedures adopted to assure that each individual in a community or country receives his due share of scarce supplies. It was first used on a large scale during World War I; to deal with massive difficulties in provisioning civilian populations, and it reappeared during World War II.

Ordinarily the price system performs the function of rationing by forcing individuals to ration their own consumption on the basis of their needs, tastes, and incomes, but in time of war or other emergency the price system is not adequate. When shortages of certain commodities are experienced or anticipated, buyers may engage in hoarding which soon can create, or magnify, the shortage and result in unfair distribution. If prices are controlled, the rationing function of price is weakened and supplies are distributed according to chance, favouritism, or on a first-come-first-served basis that is unfair to those who are left out. If prices are not controlled, they may rise so high that essential items will be beyond the reach of people with low incomes. Rationing thus becomes necessary for two main reasons: (1) to reduce the inefficiency, waste of time, and confusion entailed in leaving people to scramble, bribe, or wait long hours in line to secure what they must have; (2) to eliminate the inequity of limiting demand by letting necessities be priced so high that the relatively poor cannot afford them. The decision to ration, accordingly, is based partly on the severity of shortages, either actual or anticipated, and partly on the extent to which such scarce goods are essential to life and health. It must also be based on the degree to which sources of supply and channels of distribution can be made subject to control.

METHODS OF RATIONING

Informal Rationing.—This method of limiting consumption sometimes precedes the imposition of formal controls; it may consist of exhortations to consumers to reduce their consumption or of action by suppliers in allocating scarce supplies as they think best. For example, during World War I the U.S. Food Administration urged Americans not to eat meat on certain days; again, early in World War II, grocers limited coffee purchases to two pounds per customer. When informal rationing is practised by manufacturers or wholesalers, poor credit risks or prospective customers may be refused supplies; established customers may be limited to a percentage of their normal orders; or salesmen may be assigned quotas to allocate at their discretion. Because such devices foster favouritism and inequity they are usually superseded by formal, official rationing when shortages become really acute.

Formal rationing may take many forms, the chief of which are rationing by use, rationing by quantity, rationing by value, point rationing, and rationing of money expenditure.

Rationing by Use.—When a single commodity that is normally used for a variety of purposes becomes critically scarce, the least important uses of it may be prohibited. In late 1949, for example, New York City underwent a water shortage that forced city officials to urge economy in all uses of water and to prohibit using water to wash cars. Industrial raw materials are more frequently subjected to this form of rationing than are final consumers' goods, and when this occurs their uses are generally governed by a system of priorities.

Rationing by Quantity.—There are two ways of rationing by quantity: one is crude but effective; the other is more complicated but also more equitable. The crude way is simply to limit the

hours at which the rationed commodity is available. Hot water, for example, may be cut off at certain hours of the day to conserve fuel. In the late 1950s coffee became extremely scarce in Turkey and was informally rationed by being placed on sale only in the early hours of the morning, on certain infrequent days, and at high prices. The more sophisticated way of rationing by quantity is to assign given quotas of a commodity to all known, approved claimants. When the commodity involved is standardized, without variations in quality or form of use, like sugar, the available supply may simply be divided up among consumers who usually are issued coupons entitling them to their quota. A special problem arises with commodities that have differential importance to different categories of users. Milk, for example, is needed more by children than by adults, and gasoline has more social importance when it is used by doctors on emergency calls than when it is used for recreational driving. In such cases, consumers are classified according to their importance or need and are assigned rations accordingly.

Rationing by Value.—Some commodities are incapable of standardization because of differences in variety or quality. Quantity rationing of meat, for example, would involve periodic listing and classifying of all the varieties, grades, and kinds of meat. A more workable alternative is to limit each consumer's expenditure on such commodities and to leave him free to make his own selections within the legal limits. Because purchases must be made with money as well as with ration coupons, low prices will clear the market of the less attractive items.

Point Rationing.—A period of critical and increasing shortages, unaccompanied by proportionate reductions in consumers' incomes, aggravates the difficulty of rationing by causing individuals to substitute unrationed for rationed items, such as cheese for meat, thereby spreading shortages. As rationing is extended to more commodities the administrative burden increases and the difficulty of satisfying different individual tastes and needs becomes greater. During World War II, point rationing was introduced, first in Germany, then in Great Britain, and finally in the United States, to resolve such difficulties. Under point rationing, scarce commodities are grouped into broad categories such as meats, canned foods, or clothing. Each item within each category is assigned a point value, which may change from one ration period to another, and coupons or stamps are issued to every consumer. For example, early in World War II each consumer in Great Britain was allocated 66 clothing points which could be spent, regardless of money price, on wool socks (3 points), complete suits (32 points), wool skirts (6 points), etc. Within the limits of his money income in general, and of his point income in particular, the individual was free to allocate his expenditures as he chose. Under point rationing individuals are recipients of two kinds of income: money income and ration point income. During World War II most people spent their point incomes within each ration period, but in just the degree that rationing was effective they were likely to have money income left over.

Rationing of Money Expenditure.—Unspent money income represents a hazard to a rationed economy, as it may be used to purchase unrationed items, thereby making them scarce, or it may be used to make illicit purchases on the so-called black market. Efforts were made to deal with this problem in Great Britain and the United States by exhorting individuals to save, to purchase government bonds, and to increase their deposits in savings banks. Access to credit for the purchase of such things as household equipment was sharply curtailed. In Germany, individuals were subjected to even more intensive pressure to save. In most countries the trend of rationing during World War II was toward substituting the control of expenditure for the rationing of particular commodities, although that trend was nowhere carried to its ultimate limit, nor was there any relaxation in rationing itself until after the war.

(G. P. A.)

HISTORY OF RATIONING

Germany.—When bread rationing was first introduced in Berlin a few months after the outbreak of World War I, it was wrongly interpreted abroad as a sign of serious shortage rather than as a

precautionary measure designed to prevent maldistribution. From the outset the German system embodied the principle of differential rations. Manual workers, later divided into light, heavy, and very heavy workers, received more than the normal consumer; children under ten years, less. Rationing was administered by local authorities, who enjoyed more independence than in World War II and sometimes competed with one another for supplies. Coordination of supply and distribution by state-controlled war companies was never complete, and this opened the door to illicit trade. Evasion of the regulations from 1917 onward grew to such an extent that maldistribution of food was one of the chief factors in the collapse of the home front in 1918.

Before the outbreak of World War II thorough preparations had been made for rationing as an integral part of war economy. Rationing of bread, flour, sugar, meat, and fats was introduced in September 1939 and continued at a fairly adequate level until 1944. Further refinements were made in the system of differential rations to cover special categories of consumers. Rationing in occupied countries followed the German pattern but varied widely in efficiency and adequacy. Administration was left largely to local officials, and passive resistance by producers, traders, and consumers led to an extensive black market.

Great Britain.—Rationing was not adopted in Great Britain until near the end of World War I, when sugar was rationed. Toward the end of 1916 sugar supplies fell short of demand, and distributors were allotted only half of their 1915 supplies. Retailers were left to distribute the supply among their customers as best they could, but queues formed and discontent grew. After some months of hesitation the cabinet decided in June 1917 to introduce the first rationing scheme under which householders were invited to register with a particular shop, and retailers received supplies of sugar equal to the rations of their registered customers. A local rationing scheme for meat and fats in London and the home countries came into force on Feb. 25, 1918. On April 7 a national rationing scheme for meat was started, and on July 14 the whole population received ration books with separate cards for meat, fats, sugar, and lard. By May 1919 rationing by coupons was abolished, and sugar registration ended in November 1920. Rationing had lasted for little more than two years.

By contrast, in World War II rationing started early in 1940 and was not ended until July 1954. Ration books, which had been printed in 1938, were issued from local food offices to every individual on the basis of a special census conducted for national registration on Sept. 29, 1939. Five types of ration books were issued: for children under 5, children 5 to 18, normal adults, travelers, and seamen. Emergency cards valid for one week were issued to new arrivals or persons who had lost their books. Straight rationing, which entitled consumers to buy a fixed weekly amount of each food, was applied in 1940 to meat, bacon, sugar, fats, and tea. In 1941 cheese and preserves were added, and milk and eggs came under a scheme of priority rationing. On Dec. 1, 1941, a new system of points rationing was put into force for miscellaneous groceries, under which each consumer received a number of points to spend in each four-week period on any food in the group, each food being given a points price varying according to the expected demand in relation to the supply; thus canned salmon and dried fruits had a high points price, and cereal foods, a low price. This system was adopted after the successful introduction of points rationing for clothing and footwear. In June 1941 everyone had been given a coupon currency of 66 points, roughly corresponding to 66% of prewar average consumption. Later the figure was reduced to 48 a year. Point values for clothing were based on the amount of cloth used, but some garments were "pointed" to equate demand roughly to estimated supply. Rationing of expenditure by value coupons was rejected on the ground that it would have concentrated demand too much on the cheaper goods.

Soap rationing was introduced early in 1942 on the basis of 16 oz. per four weeks for hard soap. Chocolate and sugar confectionery were first rationed in July 1942 under what was called the personal points scheme; distribution to retailers was based on coupons collected without consumer registration. Other foods subject to controlled distribution rather than strict rationing

included milk, eggs, oranges, and fish. Milk went first to priority consumers—mothers and children up to 5 years old were guaranteed a ration of seven pints a week; children of 5 to 18 years, three and one-half pints; and schools, hospitals, and invalids also had priority supplies. The rest of the public got what was left with no definite guarantee of supply, the usual amount being two pints a week in the winter and three to four in the spring. Consumers were tied to one dairyman who received his share of the available supplies according to the number of priority and non-priority customers registered with him. Controlled distribution of shell eggs started in June 1941. Mothers and infants received priority supplies, and ordinary consumers got allocations as and when supplies permitted, varying from one a month in the winter to two or more a week in the spring. Oranges when available were sold to holders of children's ration books before other customers could be served. It was found impracticable to ration fish, but supplies to retailers were distributed as fairly as possible. Bread, flour, and potatoes were not rationed during World War II. Bread and flour rationing was introduced in July 1946 and lasted for two years; potatoes were rationed in 1947–48 when there was both a poor potato harvest and a world shortage of wheat.

In contrast with rationing schemes on the continent, differential rations for special categories of workers were kept to the minimum, and coupons did not have to be surrendered for meals in restaurants. The general principle was that everyone should be free to take meals out as a supplement to domestic rations, and caterers received an allocation of rationed foods on the basis of the number of meals served.

Food rationing in Great Britain, which ended with the decontrol of meat and bacon on July 3, 1954, was made easier by the fact that half the total food supply was imported and also by the willing cooperation of food traders and the public. There was general assent to the principle of fair shares which, though it involved some reduction in the consumption of the majority, also allowed some improvement of the diet of the poorest by means of food subsidies and welfare food schemes. (E. M. H. L.)

Soviet Union.—During the 1920s the U.S.S.R. suffered acute food shortages, partly because of the upheaval resulting from the Revolution and partly because food was shipped abroad to obtain foreign exchange. Under these circumstances, food rationing was introduced and continued until the mid-1930s. With the outbreak of World War II in 1939 food rationing was restored and continued throughout the war. (X.)

United States.—During World War I the American people were urged to exercise self-restraint in consuming scarce commodities, such as meat. Wheat flour and sugar supplies were eventually controlled by the Food Administration, headed by Herbert Hoover, to ensure maximum use of food supplies for wartime needs. Disappearing quickly after the Armistice, controls did not appear again until after the attack on Pearl Harbor, Dec. 7, 1941, when it became clear that extraordinary efforts would be needed to fight and win a two-continent war. An Office of Price Administration (OPA) had been created April 11, 1941, by executive order, to prevent "price spiraling, rising costs of living, profiteering, and inflation." Signing of the Emergency Price Control Act on Jan. 30, 1942, gave OPA specific authority to enforce its orders, including rationing.

Although OPA had an army of paid officials, much of the burden of making necessary daily decisions fell on unpaid local citizens, serving on community ration boards. Their task was made difficult by the presence of three antagonistic forces: shortages of goods; government-regulated price ceilings; and war-swollen incomes. OPA rationed some commodities according to individual need, while other items were equally available to all. Basic raw materials were controlled at first through priorities and, after mid-1943, by allocations to industrial users. The change became necessary when the word priority lost its meaning in the light of exhausted supplies. Government allocations under a Production Requirements Plan, and later a Controlled Materials Plan, were ways of dividing total supplies among essential users.

Consumer rationing was handled by several methods. In point rationing, a consumer could select from items in specific groups.

Thus small red stamps could be surrendered for meat, butter, fats, cheese, canned milk, and canned fish. Blue stamps were used for canned fruits, vegetables, and related items. Stamps were good for stated periods of time. Certificate rationing involved the use of certificates obtainable by those who could prove special need for tires, motor vehicles, and similar products. Ration coupons came to comprise a sort of currency. They passed successively from consumer to retailer to wholesaler to producer to ration authorities.

Tires were rationed almost immediately after the Emergency Price Control Act was passed, and sugar was rationed after the first general consumer registration, May 4–7, 1942. Gasoline was rationed first in the East, then throughout the country. Automobile owners with special needs established them with ration boards and were provided with additional rations; many others switched to buses, joined car pools, or relearned the joys of walking. Meats, canned goods, butter, and other foods eventually joined sugar on rationed lists. Clothing, other than shoes, was unrationed throughout the war, but scarcities developed, especially after demobilization of uniformed personnel. Fuel oil was rationed in some sections.

Immediately after the Japanese surrender in August 1945, most items were released from controls. Sugar and tires, the first to be listed, were the last to be decontrolled. OPA ceased operations on May 31, 1947, having lingered on chiefly to handle rent control and to perform final administrative acts.

The very nature of rationing could not but make it unpopular. Yet it performed the task assigned to it. The American people remained well nourished. The black market was kept to a reasonable minimum, in part because OPA in its lifetime instituted over 280,000 enforcement orders against violators of price, rent, and rationing regulations, winning 95% of its court cases. Rapid removal of controls was acclaimed, although in 1945–46 temporary scarcities and a 23% rise in prices indicated that supply had not satisfied pent-up demands.

The Korean War did not bring with it the comprehensive rationing procedures of World War II. An Office of Price Stabilization enforced a limited program of production, wage, and price controls. Chrome and other strategic materials were regulated, and the quality of appliances and motor car bumpers suffered for a time. There was evidence during and after the Korean War that leaders hoped, by planning and stockpiling of critical raw materials, to increase national self-sufficiency in the future. The report of the Materials Policy Commission, *Resources for Freedom*, five volumes (1952), was an important step. An indication that future rationing, if any, might vary from the patterns of earlier years could be found in the continuing farm surpluses and in constantly expanding industrial facilities. (V. D. B.)

RATLAM, a town and district in the Indore division of Madhya Pradesh, India. The town, headquarters of the district, lies 65 mi. NW of Indore. Pop. (1961) 87,472. It is the divisional headquarters of the Western Railway and an important industrial centre with a cotton textile mill, strawboard factory, and pottery works. A government college is affiliated to Vikram University.

RATLAM DISTRICT (area 1,727 sq.mi. [4,473 sq.km.]; pop. [1961] 483,521) corresponds with the former princely state of Ratlam. It has fertile black cotton soil producing wheat, maize (corn), and sugarcane, and about 6% of the district is forested. Vindhyan sandstone is quarried for building purposes. Jaora (pop. 31,140), to the north, has a sugar mill, a college, and a polytechnic. The people speak Malwi, a dialect of Hindi.

The former princely state of Ratlam was founded by Ratan Singh Rathor (a great-grandson of Raja Uday Singh, maharaja of Jodhpur), who died fighting against Aurangzeb in 1658.

(D. G. NA.)

RATNAGIRI, a town and district in the Bombay division of Maharashtra, India. The town, headquarters of the district, lies on the Arabian Sea, 136 mi. (219 km.) S of Bombay. Pop. (1961) 31,091. Places of interest include the Ratnagiri Fort (1500), Lokmanya Tilak Memorial, and the Thebaw Palace (1911). The Gogate Arts and Science College is affiliated to Poona University; other institutions include a teachers' training college for men, an industrial training institute, and the Marine Biological Research Station. Ratnagiri has no railway but is served by bus and steamer services.

RATNAGIRI DISTRICT (area 5,025 sq.mi. [13,015 sq.km.]; pop. [1961] 1,827,203), forms a rugged and rocky strip between the Western Ghats and the sea. Near the coast the district is intersected by creeks and navigable rivers along which lie the chief ports and almost all the fertile land. The main crops are rice, mangoes, and coconuts; sunn hemp is also grown. Grain, cotton, and sugar are the chief imports and coconuts, salt, mangoes, and dried fish the exports. The district is served by road only. The principal towns include Chiplun, Malvan, Sawantwadi, and Vengurla. (M. R. P.)

RATNAPURA ("the City of Gems"), chief town in the province of Sabaragamuwa, Ceylon, lies 40 mi. (64 km.) SE of Colombo. Pop. (1963) 21,582. It is the commercial and administrative centre of a region which has long been renowned for precious stones including rubies, sapphires, and cat's-eyes. These are dug from valley alluvium and prepared by Muslim gem cutters. The town is dominated by a hill on which the Portuguese built a fort. It has good road connections with Colombo and lies on a narrow-gauge railway.

The administrative district of Ratnapura is characterized by great diversity; it ranges from the valley lowlands of the Kalu Ganga to the range that culminates in Adam's Peak (7,360 ft.) and from a very wet west to dry zone conditions in the east. Rubber and rice production are economically more important than gems. The population (1963) was 547,494, with Kandyan Sinhalese in the majority. (B. H. F.)

RATRANMUS (fl. c. 860), priest and monk of the abbey of Corbie, near Amiens, in France, remembered for his part in the 9th-century Eucharistic controversy, is little known apart from his works. He composed one book on the virgin birth, another on predestination—predestination to sin is rejected but predestination to salvation is not—and to his contemporaries his principal contribution must have seemed the four books in which he defended the Western Church from attacks by Photius, patriarch of Constantinople, at the time of the Filioque controversy. (See CREED: *Nicene Creed: Filioque Clause*.) In the judgment of posterity, however, much more importance should be attached to the short work of remarkable originality, *Christ's Body and Blood*, which is, at least in part, an irenic reply to *The Lord's Body and Blood* written by his abbot, Paschasius Radbertus (q.v.).

Ratramnus' position is this: the bread and wine are mystic symbols commemorative of Christ's body and blood, becoming such through sacerdotal consecration but retaining their outward appearance and remaining to the senses merely bread and wine. Within them, however, resides a power perceived only by faith, and this is what makes them effective. They are not Christ's body and blood *in truth* (perceptible to the senses), but *in a figure*, that is, symbolically. This doctrine he supports by appeal to the Scriptures, to several of the Fathers, and by citation of two prayers found in the missal of his day.

These views contrast strongly with those of Paschasius, but the book does not appear to have undergone attack until the controversy involving Berengar (q.v.) of Tours, when it was ordered destroyed at a synod held at Vercelli in 1050, later condemned again at the Lateran in 1059, both times wrongly supposed to be by Johannes Scotus Erigena. Copies survived, however, and the book had its influence at the time of the Reformation; e.g., at his trial in 1555 Bishop Nicholas Ridley said of Ratramnus that he "was the first that pulled me by the ear, and forced me . . . to a more diligent search of Scripture. . ."

RATTLESNAKE, any of a number of venomous snakes having a tail rattle that produces a buzzing or hissing sound when vibrated. Rattlesnakes belong to two genera, *Crotalus* (rattlers proper) and *Sistrurus* (pigmy rattlers and massasaugas); both genera belong to the pit viper family (Crotalidae).

JOHN E. WERLER, HOUSTON ZOOLOGICAL GARDENS

MEXICAN GROUND RATTLESNAKE (*SISTRURUS RAVUS*)

Rattlesnakes occur only in the Americas, from southern Canada to central Argentina. They are found in a wide variety of habitats but most species prefer arid regions. Although they swim readily and occasionally climb trees, no species is habitually aquatic or arboreal.

Rattlesnake species (numbering 30, with many subspecies) differ greatly in size, appearance, and degree of danger. The largest is the eastern diamondback (*C. adamanteus*) of the southeastern states, sometimes attaining a length of 8 ft. and a weight up to 24 lb. The western diamondback (*C. atrox*), Texas to southeastern California, is only slightly smaller. At the other extreme are several Mexican species of *Crotalus* whose adults rarely reach two feet or a weight of three ounces. Although a few species are marked with transverse bands, most are blotched with dark diamonds, hexagons, or spots on a lighter background, usually of gray or light brown; some are characterized by various shades of orange, pink, red, or green.

The rattle, long the subject of myth and fanciful story, tends to frighten or warn creatures that might harm the snake. The sound is produced by transverse vibrations of the tail; the speed of vibration varies with the temperature, but averages about 48 cycles per second. If the snake is large, the sound can be heard at a distance of 200 ft. or more. The rattles, composed of the horny material keratin, are loosely interlocked; a new segment is produced with each skin shedding, not annually, as was once believed, but three or four times a year in young snakes, and about twice a year in adults. Rattles are subject to loss by wear and breakage, so very long strings are rare, even in aged snakes. An adult usually has from six to ten rattle segments. Although most rattlesnakes, when annoyed or alarmed, rattle before they strike, this is by no means a universal habit.

Rattlesnakes have a moderately keen sense of vision, particularly for nearby moving objects. The chemoreceptive sense, however, is acute, with dual avenues: olfactory nerves from the nostrils; and the tongue tips, which carry exterior particles or odours to sensing organs in the roof of the mouth. The rattlesnake has no sense of hearing, but is extremely alert to ground tremors, and can sense the approach of a horse or a man at a considerable distance. Like all pit vipers, the rattlesnake has facial pits, organs of an acute sensitivity to fine differences in heat, an especially valuable faculty for preying on small ("warm-blooded") mammals.

As in other reptiles, the body temperature of a rattlesnake is dependent on external conditions: air and ground temperatures, and impinging radiation. A rattlesnake seeks refuge when its body temperature falls below 13° C (55° F) or approaches 38° C

(100° F.). Throughout life the snake adjusts both its seasonal and daily activities to escape these dangerous temperature extremes. In autumn, rattlers congregate deep in rock slides or crevices, where they will be protected in winter from freezing and enemies; and in summer, when diurnal temperatures are dangerously high, they become nocturnal, taking refuge in burrows of mammals or in other places away from the sun's rays and the hot ground. Rattlers are likely to be abroad and most active when the external conditions produce body temperatures within the range 24°–27° C (75°–80° F).

Most rattlesnakes subsist on small mammals, particularly rodents. The young of large rattlers and adults of small species depend largely on lizards. Birds and birds' eggs, amphibians, and arthropods are sometimes eaten. Rattlers feed at intervals of about ten days, and secure their food either by lying in wait along a trail frequented by prey or by tracking prey into a hole or nest. The strike is sudden; the venom not only kills small prey quickly, preventing a retaliatory bite, but also aids in digestion.

Rattlesnakes mate in the spring, and the young are born in the autumn. Broods usually comprise from 3 to 12 young. Some tropical species are relatively prolific, bearing up to 60 young. The newborn rattler is encased in a fetal membrane, which it slits with an egg tooth. The mother leaves the young within a few hours, exercising no parental care or protection. Despite a popular supposition, rattlers are not usually found in pairs; they separate after mating. The average life span is probably 10–12 years; captive specimens have lived up to 23 years.

Rattlesnakes are preyed upon by coyotes, foxes, wildcats, and badgers; by hawks and roadrunners; and, among the reptiles, by king snakes and racers. Although king snakes readily eat young rattlers (they are immune to venom) they do not seek out and destroy rattlers larger than they can swallow, as is often supposed. Deer, antelope, and goats sometimes kill rattlers by deliberately stamping on them with their hooves. Among domestic animals, hogs have been used with some success in rattlesnake control. But by far the greatest killer of rattlesnakes is man and the crushing wheels of his motor vehicles.

All rattlesnakes are venomous and dangerous. Because of improved methods of treatment, and with the abandonment of hazardous folklore cures, the bite of a rattlesnake today is not the threat to life that it was in colonial and pioneer days. Nevertheless, rattlesnake bite is a serious and painful accident, one not to be trifled with, especially if the victim is a child. Of the several thousand people bitten annually in the United States by rattlesnakes less than 1% of the cases prove fatal. The danger from rattlesnake bite depends on many factors, including the site of the bite, for the closer to the trunk, the more urgent is the need for treatment; the size of the snake, for larger snakes have more venom and longer fangs, which penetrate clothing easier; and finally the kind of rattlesnake, for different species have venoms that vary in toxicity. The most dangerous rattlesnakes are the South American rattler (*C. durissus terrificus*) and its relatives; these snakes are notable for a venom that attacks the nervous system. The most dangerous rattlers found in the United States, the diamondbacks, have a venom that attacks blood vessels and muscles primarily. Approved treatment involves the use of a tourniquet, incision and suction in the field, and early administration of antivenin. If a doctor can be reached within a half hour, field incisions should be omitted. Alcoholic stimulants and exertion by the victim should be avoided.

Rattlesnakes are not of great importance commercially. There is a small but continuous demand for live snakes by carnivals, roadside stands, and zoos. Skins and novelties made from skins are sold. Venoms are required in only small amounts by manufacturers of antivenin. Although therapeutic uses of rattlesnake venom were once considered promising, they have not fulfilled expectations. See also SNAKE.

See L. M. Klauber, *Rattlesnakes*, 2 vol. (1956). (L. M. Kr.)

RATZEL, FRIEDRICH (1844–1904), German geographer whose work shows the strong influence of the 19th-century interest in evolution. He was born at Karlsruhe on Aug. 30, 1844. During his youth he worked as an assistant in pharmacies, thereafter study-

ing zoology at the universities of Heidelberg and Jena. After obtaining his degree, Ratzel became travel correspondent for the *Kölnische Zeitung* and always retained the outlook and energy of a journalist. This work was interrupted by the Franco-German War, in which he served with distinction and was severely wounded. He then traveled for the *Kölnische Zeitung* in Europe and in the New World. His accounts of the U.S. and Mexico in the 1870s remain classics of descriptive writing, evincing his interest in the relationships between the European immigrants and other racial groups.

In 1875 Ratzel was appointed lecturer in geography at the Technical High School at Munich, becoming professor in 1880. At Munich he gained repute through his descriptive accounts of the U.S. and Mexico; the first volume of his *Anthropogeographie*; and his long treatise *Völkerkunde*, translated as the *History of Mankind*. In 1886 Ratzel became professor of geography at Leipzig. Much of his work there was political geography with a strong philosophical strain. His publications included *Politische Geographie*, *Die Erde und das Leben*, and a political-geographical study of the United States. His short essay *Lebensraum* (1901), often cited as a starting point of geopolitics, was in fact mainly a tentative study in biogeography. He died at Ammerland on Aug. 9, 1904.

Ratzel has been much criticized as a geographer, largely because subsequent misuse of his teaching was associated with German tyranny. Much of his work was controversial both politically and academically. A boisterous and somewhat naive nationalist but also an upright scholar, Ratzel sought both to integrate geographical work and to align it with contemporary thought. (H. G. S.)

RATZENHOFER, GUSTAV (1842–1904), Austrian sociologist and army officer, who conceived of society as a universe of conflicting ethnic groups, was born in Vienna on July 4, 1842. Ratzenhofer became a cadet at the age of 17 and rose rapidly in the military. Already a voracious reader, he had more opportunity for study when he became director of the army archives in 1878. After subsequent service as chief of the general staff of an army, in 1898 he became field marshal and president of the supreme military court of Vienna.

Intellectually and professionally a tough self-made man, Ratzenhofer was naturally inclined to apply Darwin's biological theory of the struggle for existence and survival of the fittest to human society. Thus he joined the ranks of the social Darwinists who carried Darwin's theory of biological evolution of organisms into sociology by explaining the origin of ever larger social groups as a gradual development from less complex groups in conflict. Ratzenhofer, following his fellow Austrian, L. Gumplowicz, chose racial groups as the units for analysis. As might be expected from a sociologist at the top of the military hierarchy, Ratzenhofer believed that political science must rule society. He thought sociology could engineer the human species to even higher forms of social association.

See Robert Schmid, "Gustav Ratzenhofer: Sociological Positivism and the Theory of Social Interests" in *An Introduction to the History of Sociology*, ed. by H. E. Barnes, with bibliography (1948). The life of Ratzenhofer is given in his posthumous work, *Sociologie* (1908), ed. by his son. (H. S.; X.)

RAU, SIR (BENEGAL) NARSING (NARSINGA) (1887–1953), Indian lawyer, diplomat, and administrator, who helped draft the Indian constitution of 1950, was born in Mangalore on Feb. 26, 1887. Graduate of the universities of Madras and Cambridge, he entered the Indian civil service in 1910 where he achieved distinction as a jurist by his revision of the entire Indian statute book (1935–37). He served as a judge of the High Court of Calcutta (1939–44). As the preeminent jurist of India he became constitutional adviser to the constituent assembly (1946–49); also for Burma in 1947 in drafting its constitution. His writings on Indian law include a noted study on constitutional precedents as well as articles on human rights in India. Rau headed the Indian delegation at several sessions of the United Nations General Assembly and was permanent representative of India to the United Nations from 1949 to 1951. He served as vice-chairman of the International Law Commission, and in 1951 was elected a judge of the International Court of Justice at The Hague. He died on Nov. 29, 1953, in Zürich, Switz. (Or. S.)

RAUSCHENBUSCH, WALTER (1861–1918), U.S. clergyman, professor of theology, and social reformer, a leader of the Social Gospel movement, was born in Rochester, N.Y., Oct. 4, 1861, the son of a Lutheran missionary among German immigrants in the United States, who had become a Baptist and had been engaged to train a German-speaking ministry at the Rochester Theological Seminary. After graduating from the Rochester Free Academy, Rauschenbusch studied for four years in Germany and then returned to Rochester in 1883, taking simultaneously his final year at the University of Rochester (B.A., 1884) and his first year at the theological seminary. On June 1, 1886, following the completion of his theological studies, he became minister of the Second German Baptist Church in New York City. There he was awakened to the social problem by the personal distress he encountered in a depressed neighbourhood and by the influence of Henry George's campaign for mayor. An even more important influence was exerted by two other young Baptist preachers, Leighton Williams and Nathaniel Schmidt. The three young men formed themselves into a Society of Jesus, which was later to be expanded into the influential Brotherhood of the Kingdom. *For the Right*, a monthly periodical published "in the interests of the working people," was launched in November 1889 in an effort to reach the labouring classes and to aid in the formulation of a Christian Socialist program. Publication ceased in March 1891 when Rauschenbusch left for a year's study in Germany. In 1897 he was called to the faculty of the Rochester Theological Seminary and in 1902 was installed as professor of church history. The publication of *Christianity and the Social Crisis* (1907) won him national acclaim as the major spokesman of the social gospel. He died, saddened by World War I, on July 25, 1918.

Rauschenbusch always regarded himself as an evangelist, seeking to win men to a "new birth" in Christ and to put them to work in the interests of his kingdom. He seized upon the "kingdom of God" as the only concept adequate to induce repentance and to harness the impulses of new spiritual life. He had little patience with contemporary optimistic views of human nature. "Ethically," he said, "man sags downward by nature. It is ever easy to follow temptation and hard to resist it. The way that leads to destruction is always broad and its asphalt pavement is kept in perfect order, with toboggan slides at either side for those who prefer a steeper grade." Among his other important writings are *Prayers for the Social Awakening* (1910), *Christianizing the Social Order* (1912), and *A Theology for the Social Gospel* (1917). See also **CHRISTIAN SOCIALISM**.

See D. R. Sharpe, *Walter Rauschenbusch* (1942). (W. S. H.)

RAVAISSON-MOLLIEN, JEAN GASPARD FÉLIX (1813–1900), French philosopher and connoisseur, commonly known as FÉLIX RAVAISSON, was born at Namur on Oct. 23, 1813. A protégé of the comte de Salvandy, minister of education, he was taken from a teaching post in Rennes to be inspector general of public libraries (1839–45, 1846–53). Under Napoleon III he was made inspector general of higher education, a title which he retained till 1888, though from 1870 he was curator of antiquities in the Louvre. He died in Paris on May 18, 1900.

His major philosophical works are *Essai sur la métaphysique d'Aristote*, two volumes (1837–46); *De l'habitude* (1838; new ed., 1927); and *La Philosophie en France au XIX^e siècle* (1868; 3rd ed., 1889). As a philosopher Ravaisson belonged to the school of Victor Cousin (*q.v.*), with whom, however, he was at issue on many important points. The act of consciousness, according to him, is the basis of all knowledge. His influence was extensive in the Latin Catholic world, where it did much to prepare for Bergsonism (see **BERGSON, HENRI**).

See his *Testament philosophique et fragments*, ed. by Charles De-vivaise (1933); also J. Dopp, *Félix Ravaisson: la formation de sa pensée d'après des documents inédits* (1933).

RAVEL, (JOSEPH) MAURICE (1875–1937), one of the most original French composers of his time. Of mixed Swiss-Basque descent (Swiss on his father's side, Basque on his mother's), he was born at Ciboure, near Saint-Jean-de-Luz, Basses-Pyrénées, on March 7, 1875. While still a student at the Paris Conservatoire, which he entered at the age of 14, he published a *Menuet antique*

BY COURTESY OF THE FRENCH EMBASSY, LONDON; PHOTOGRAPH, LIPNITZKI

MAURICE RAVEL

composition since 1898. By the time Ravel was 30 he had already published his String Quartet (1903), the song-cycle *Shéhérazade*, the Sonatina and *Miroirs* for piano, and the *Introduction et Allegro* for harp, string quartet, flute, and clarinet. One of his earliest piano pieces, *Jeux d'eau* ("Fountains"; 1901), inaugurates a new era in the use of the piano's technical resources, and toward the end of his life, in 1931, he wrote two piano concertos, one of which, for the left hand only, is among his most original works. Several of his piano works were later orchestrated by him, notably *Ma Mère l'Oye* ("Mother Goose") and *Valses nobles et sentimentales*. Ravel died in Paris on Dec. 28, 1937.

His chamber works include a remarkable trio for violin, cello, and piano, a violin and piano sonata, and a sonata for violin and cello, but it was in his symphonic works, the *Rapsodie Espagnole*, the ballet *Daphnis et Chloé* (1909–12), and *Boléro* (1927, performed 1928) that he reached his height. As a songwriter Ravel achieved great distinction with his imaginative *Histoires Naturelles* (1906), *Trois Poèmes de Mallarmé* (1913), and *Chansons Madécasses* (1925–26). In opera he produced two little masterpieces of wit and fantasy, *L'Heure Espagnole* (1907) and, in collaboration with Colette as librettist, *L'Enfant et les sortilèges* (1925).

In everything he wrote Ravel was an exquisite craftsman, striving always for perfection of form and style which he judged more valuable than an expression of personal feelings. Though he worked in the classical form and was never a revolutionary musician, he created an individual harmonic language as unmistakably his own as any page of Bach or Chopin. Although it is incorrect to bracket him with Debussy, the two composers nevertheless had certain features in common, notably their attraction to Baudelaire and Mallarmé, and a delight in rare and precious sensations. In temperament, however, and in methods and technique they were vastly different. A highly distinctive composer in everything he wrote, Ravel, as Roland-Manuel wrote, "is one of the rare French composers who have left so strong an imprint on their art that music after them can never be the same as it was before they appeared on the scene."

RAVEN, among the largest of the perching birds, and, with crows, magpies, and jays, a member of the family Corvidae. Of all corvids, the ravens appear to be the most intelligent and the most advanced in imitative skills. Long before it was immortalized in Poe's "The Raven," the common raven (*Corvus corax*) was an almost universal symbol of dark prophecy—of death, pestilence, disease. But its cleverness, appearance, and fearless habits have won it a degree of admiration, as evidenced by its noble heraldic

for piano (1895), some songs, and the *Pavane pour une infante défunte* ("Pavane for a Dead Princess") for piano (1899), which established his reputation almost overnight, although he judged it severely in later life. His failure, after three attempts, to win the coveted Prix de Rome for composition—the works he submitted having been judged too advanced by the conservative members of the jury—caused a scandal. Indignant protests were published and liberal-minded musicians and writers, including Romain Rolland, supported Ravel, denouncing the narrow-mindedness of his judges. As a result, in 1905 the director of the Conservatoire, Théodore Dubois, was forced to resign and his place was taken by Gabriel Fauré, with whom Ravel had been studying

A NORTHERN SUBSPECIES OF COMMON RAVEN (*CORVUS CORAX PRINCIPALIS*)

roles in the mythology of some peoples.

Although much like the crow (*c.v.*) in appearance, the common raven is considerably larger—with a length of 22–25 in. and a wingspread of more than 4 ft.—has a much heavier bill, and shaggier plumage, especially about the throat. The lustrous black feathers have a blue or purplish iridescence. In the white-necked raven (*C. cryptoleucus*), a crow-sized bird of western North America, the bases of the neck feathers are white, and show only when the feathers are ruffled, as in display or by the wind.

Formerly abundant throughout the Northern Hemisphere, the raven is now restricted to the wilder, undisturbed parts of its range where it is free of persecution by man. It is among the hardest of birds, inhabiting the northern tundra and coniferous forests as well as barren mountains and desert. Being keen-sighted, sagacious, and notably wary, the raven survives by its wits; it has never been protected by law.

Like other corvids, the raven is a noisy, aggressive omnivore whose diet includes rodents, insects, grain, and birds' eggs. In winter, especially, it is essentially a scavenger, and feeds on carrion, dead fish, and other refuse. To some extent it also preys on sick animals, both wild and domestic. Its calls include guttural croaks, gurglings, and a sharp metallic "tok." Ravens breed as early as January in some areas and as late as April elsewhere. The spectacular courtship flight involves soaring and all manner of aerial acrobatics. The crudely made nest, of coarse sticks, usually lined with hair or shredded bark, is a bulky structure up to five feet in diameter; it may be built on a cliff or near the top of a large tree. The three to seven eggs, pale green or gray, and streaked, spotted, or blotched with brown, are incubated for about three weeks. The young remain in the nest for about a month. If captured while a nestling, a raven may make an interesting pet capable of learning to mimic a few words. The record life span reported for a raven in captivity is 69 years; most individuals perhaps do not live to even half that age in nature. (E. R. BE.)

RAVENNA, a city and archiepiscopal see of Emilia-Romagna, northeastern Italy, and capital of the province of Ravenna, lies 52 mi. (84 km.) E of Bologna by rail and 30 mi. (48 km.) NW of Rimini, on a low-lying plain near the confluence of the Ronco and Montone rivers, 6 mi. (10 km.) inland from the Adriatic Sea. It is connected by canal with the seaside resort of Marina di Ravenna, 6 mi. NE, which has developed round the old Porto Corsini. Pop. (1961) 116,273 (commune).

Of the ancient Roman city and port of Ravenna with its harbour

(*Classis*) nothing is now visible. The fame of Ravenna rests on the quality and quantity of its 5th–8th-century Christian monuments, which in many respects surpass those of Rome itself. As capital city of the Western Roman Empire for two and a half centuries and a major port of entry for the Eastern Empire, Christian Ravenna reflects in its art the methods, designs, and imagery of West and East alike. The result is a sophisticated and often highly individual art, which gains added importance from the relative scarcity of comparable contemporary monuments in Milan and Constantinople, the two cities with which Ravenna was in closest contact.

The Monuments.—The earliest period of Ravenna's greatness, dating from the residence there of the emperor Honorius early in the 5th century A.D., has left the so-called mausoleum of Honorius' sister, Galla Placidia (d. 450), in the northwest of the city. This was originally related to the adjacent basilica of Sta. Croce, now destroyed. Its building technique is Western, but its architectural composition, a Latin cross with barrel vaults and central dome, has Eastern prototypes. The whole upper surface of the interior is covered with mosaics, mostly with a blue ground. The central dome is decorated with a cross and the beasts of the four evangelists—a scheme echoed in the archbishop's palace (chapel of S. Pier Crisologo), in the basilica of S. Vitale, and later, at Rome, in Sta. Prassede (chapel of S. Zeno). Off the Piazza del Duomo to the south is the "orthodox baptistery" (S. Giovanni in Fonte, late 4th century), also known as the Neon baptistery from the tradition that it was decorated by Archbishop Neon (449–452). The use of stucco is combined with mosaic; the architectural motifs and the procession of apostles round the dome are of outstanding quality. The churches of S. Giovanni Evangelista, S. Francesco (with Dante's tomb [1780]; founded in the 5th century as S. Pietro Maggiore), Sta. Agata, and S. Vittore are also of this early period but have been considerably altered; of S. Giovanni Battista little remains.

Of the monuments of the time of the Arian Ostrogothic emperor Theodoric (d. 526), the most impressive is his mausoleum. This is two-storied, decagonal outside and circular within, and covered by a monolithic dome 36 ft. (11 m.) in diameter, made of limestone imported from Istria. On the capture of the city by the Catholic Belisarius in 540, the bones of Theodoric were scattered and the mausoleum converted into the church of Sta. Maria della Rotonda. The Arian baptistery (now Sta. Maria in Cosmedin and next to S. Spirito, or S. Teodoro), of the same period, northeast of the town centre, has a mosaic in the dome. This, although much restored, is interesting as showing a simplified version of the mosaic of the Neon baptistery, rationalized by the introduction of the *Etoimasia* (i.e., the gospels enthroned) as the goal of the procession of apostles.

S. Apollinare Nuovo.—To the period of Arian domination belongs also the older part of the mosaic decoration of the early-6th-century basilica of S. Apollinare Nuovo (southwest of the railway station, on the east side of the city). This, originally an Arian cathedral, became a Catholic church about 570 and was dedicated to St. Apollinaris in the 9th century when the saint's remains were brought from his other basilica at Classe. It contains magnificent mosaics. From its Arian phase date the representations of Theodoric's palace and of the city of Ravenna (on the right) and of the port of *Classis* (on the left), as well as the two cycles, now high on the walls, of the teaching and miracles of Christ (left hand, showing Christ beardless) and his passion and resurrection (right hand, omitting the crucifixion). These are among the oldest of such representations in existence, even if not the first, and are thus of considerable artistic and theological interest. The Catholics completed the decoration of S. Apollinare Nuovo. Above the arcades of the presbytery are, on the right-hand side, a row of men saints with wreaths proceeding from Ravenna toward Christ enthroned with attendant angels; and, on the left-hand side, a row of women saints proceeding from *Classis* toward the Virgin and Child with Magi. Above the figures are conchs in mosaic (not stucco, as in the Neon baptistery).

S. Vitale.—In the time of Justinian (mid-6th century) S. Vitale, just southwest of Galla Placidia's mausoleum, also was completed.

The form of this church, an octagonal martyrium with a presbytery and seven semicircular niches opening through arcades into a two-storied ambulatory, is akin to that of the almost contemporary church of SS. Sergius and Bacchus in Constantinople. The marble for both churches came from the quarries of Proconnesus on the Sea of Marmara and was perhaps carved by the same workmen; but the use in S. Vitale of an extra, crudely carved impost block above the impost capital shows that the builders did not understand the purpose of this Byzantine innovation. The construction of the lofty dome with terracotta tubes, a method used also in Galla Placidia's mausoleum and in the Neon baptistery, is another feature with no Eastern equivalent. The famous mosaics are all in the presbytery. They are the only ones in Ravenna to show at all strongly the influence of Constantinople; the masters were, however, almost certainly not Greek but from a local school. The mosaics are arranged in panels (each treated independently) whose size and shape are dictated by the architectural forms. In the semidome of the apse Christ is depicted enthroned on the globe of the world with supporting angels; St. Vitalis appears on the right, and on the left Bishop Ecclesius with a model of the church. On the left-hand wall is Justinian accompanied by attendants including Archbishop Maximian; on the right-hand wall is Theodora with court ladies. Christ is shown also with apostles and SS. Gervase and Protase, reputed to be the sons of St. Vitalis, on the triumphal arch. On the right are the sacrifices of Abel and of Melchizedek, the prophet Isaiah, and Moses at the burning bush. On the left are Abraham entertaining the three angels and sacrificing Isaac, the prophet Jeremiah, and Moses on Mt. Sinai. The pair of panels showing Justinian and Theodora with their retinues are important documents of imperial costume and portraiture. The figure, in Justinian's following, of Archbishop Maximian is named; his monogram appears also on the front of his ivory throne, now in the archiepiscopal museum behind the cathedral. The carvings on this chair are of great historical, theological, and liturgical interest. The fine panels show the four evangelists and the Baptist with scenes from the life of Joseph and the life of Christ, in a framework richly carved with animals and birds in a vine scroll. The panels are generally thought to be the product of a workshop in Constantinople.

Other Monuments.—The basilica of S. Apollinare in Classe, three miles south of Ravenna near the site of the ancient Classis, was consecrated in 549. Eastern influence has been deduced from the external polygonal form of its apses and apsidal chapels. Its capitals were certainly imported. The fine apse mosaic portrays St. Apollinaris, the first bishop of Ravenna, in prayer beneath a symbolic representation of the Transfiguration of Christ. The other mosaics are later and have been heavily restored.

The oldest church in Ravenna is the cathedral, southwest of the city centre, built originally in 370–390 and dedicated to its founder, St. Ursus. It was destroyed in 1733 and at once rebuilt (1734–43); of the old structure only the crypt, the pulpit of Archbishop Agnellus (556), and a later campanile survived.

Ravenna has several distinctive round campaniles of red brick (the usual material of the area); they are generally later in date than the churches for which they were built. That of S. Apollinare Nuovo (870–878) provides the earliest example in Italy of the decorative use of majolica. Those of S. Apollinare in Classe, Sta. Maria Maggiore, and Sta. Agata are also of the 9th century. S. Giovanni Evangelista and S. Francesco have square campaniles of the 10th century.

Sta. Maria in Porto and S. Vitale have 16th-century cloisters of the Venetian period. Incorporated in those of the latter is the Museo Nazionale d'Antichità, containing an important collection of classical and early Christian antiquities: inscriptions, icons, ceramics, and sculptures, which include ivories, screen panels, and sarcophagi. These last, both in the museum and in the churches, are outstanding. Some of the figured pieces may be imports or the work of immigrant craftsmen, but those with north Italian animal symbolism seem almost all to have been made locally. Typical is the design of peacocks or lambs with a cross, which in the 8th century spread throughout Italy. It is probable that Ravenna was a centre of ivory carving up to the 6th century. Modern excava-

tions have revealed remains of floor mosaics in S. Giovanni Evangelista. S. Vitale has a magnificent floor of *opus sectile* marble inlay, as well as rich wall paneling of coloured marble and intarsia.

Sta. Maria in Porto Fuori, built after 1069, was, until its destruction in World War II (1944), the only important surviving building of the later Middle Ages. The only remaining early civil building is the elaborate facade of what is usually identified as the palace of the exarchs (south of S. Apollinare Nuovo). Excavation has revealed decorative floor mosaics there, too, as well as nearby foundations which may be those of the palace of Theodoric.

The influence of Ravenna upon art and architecture was widespread. In Milan, S. Lorenzo is supposed to have been constructed on the orders of Galla Placidia; in Rome, she gave mosaics for S. Paolo fuori le Mura. It is likely that other work in Rome was executed by artists of Ravenna during the time of Justinian. Later, Charlemagne carried off to Aachen (Aix-la-Chapelle) the brazen statue of Theodoric and columns from his palace.

The Modern Town.—Mosaic work continues in Ravenna; the Accademia di Belle Arti south of the city centre houses a school for the study and production of mosaics as well as a collection of works by painters of the Romagna. The centre itself has the Teatro Alighieri (1840–52), the Piazza del Popolo and, alongside it, the medieval Palazzo Comunale fronted by two columns by Pietro Lombardi (1483). South of the station and adjacent to Sta. Maria in Porto are public gardens and east of these, across the railway line, is a race track.

Outside Ravenna, east of S. Apollinare in Classe, is the celebrated ancient pine forest (Pineta di Classe; much reduced in size), which was admired by the poet Byron when residing in Ravenna at the palazzo Guiccioli (1821), and which was the refuge in 1849 of Garibaldi and his wife Anita, who died there.

Ravenna is a junction for the main road and railway routes from Ferrara to Rimini and down the Adriatic coastline. Its formerly marshy surroundings have been made into well-drained agricultural land, and it is a centre for the sale of local produce (cereals, fruit, sugar beet, hemp). Wine, macaroni, fertilizers, cement, and furniture are made. There is an important methane extraction and processing plant which has led to the growth of a large industrial quarter and to considerable immigration. The quarter around the railway station was rebuilt after severe damage in World War II (1944), and considerable rebuilding in the city centre, in addition to suburban development, reflects the city's present affluence.

RAVENNA PROVINCE (area 718 sq.mi. [1,860 sq.km.]; pop. [1961] 328,969) is bounded north by Ferrara province, west by Bologna, south by Forlì and east by the Adriatic Sea. Most of it consists of plain, once marshy but now reclaimed for agriculture, but the land rises in the southwest to the foothills of the Tuscan-Emilian Apennines. The province is watered by the Reno, Santerno, Senio, and Lamone rivers, as well as by the Ronco and Montone. The chief occupation is agriculture. There are salt-works at Cervia, on the coast southeast of Ravenna city; and some industry at Lugo in the west of the province and at Faenza to the south.

HISTORY

In prehistoric times Ravenna was a modest island settlement protected by coastal lagoons. Its importance dates from the decline of the neighbouring sites of Spina (*q.v.*) and Adria. It passed under Roman control in 191 B.C. and was the base from which Julius Caesar negotiated with the Senate in 50–49 B.C. before crossing the Rubicon River to the south, so starting the civil war. Augustus built the harbour, Portus Classis, and made Ravenna the base for his Adriatic fleet. An aqueduct 23 mi. long (of which traces remain) was built by Trajan and restored by Justinian. Early in the 5th century A.D. the barbarian invasions caused the emperor of the west, Flavius Honorius (reigned 395–423), to withdraw his court from Rome to the safety of Ravenna; and the city was the capital of the Western Empire until its dissolution in 476 with the accession of the first barbarian ruler of Italy, Odoacer. He in turn surrendered Ravenna to the Ostrogoth Theodoric in 493, and the latter made it the capital of the Ostrogothic kingdom.

In 540, Ravenna was surrendered to Belisarius, Byzantine general of the emperor Justinian I the Great, and subsequently made an imperial exarchate (*see* RAVENNA, EXARCHATE OF). From the time of Honorius, Ravenna had enjoyed great political, economic, intellectual, and artistic activity. It had been raised to the rank of archbishopric in 438 and had an important mint. About 751 it fell to the Lombards, but was taken from them by the Frankish king Pepin III the Short, who handed it over to the pope in 757, the archbishops, however, retaining almost princely powers. A short-lived bid for independence in the 12th century was followed, in the 13th–14th centuries, by subjection to the house of Da Polenta, a noble family of the Romagna. From 1441 to 1509, Ravenna was under Venetian control and briefly, after the battle and sacking of 1512 (*see* below), under the French. Thereafter until 1860, when it joined united Italy, it was subject to the popes with only minor interruptions.

The patron saint of Ravenna is the early martyr St. Vitalis, of whom nothing certain is known. Its first bishop was St. Apollinaris, also reputed a martyr; there is no reliable evidence to confirm the tradition that he was a disciple of St. Peter. Archbishop at the time of Galla Placidia was St. Peter Chrysologus (the "golden orator," c. 400/406–c. 450), who had Placidia's support for his building projects. St. Romuald (c. 950–1027), founder of the Camaldolese hermit-monks, was a member of the Onesti ducal family of Ravenna and was born there; so also was the Camaldolese St. Peter Damian (1007–72).

Battle of Ravenna, 1512.—Pope Julius II, resentful of French power in northern Italy and anxious to aggrandize the Papal States by annexing the French-protected dukedom of Ferrara, had proclaimed in 1511 a Holy League with Spain and Venice. The army of Louis XII of France (which included a German element), boldly led by the 23-year-old Gaston de Foix, followed a successful defense of Bologna early in 1512 with an assault on Ravenna in April. The Spanish viceroy, Ramon de Cardona, who had been anxious to avoid a pitched battle, took up a strong defensive position south of the Ronco River, which Gaston crossed on April 11, Easter Day. During the cannonade which opened the battle many French captains were killed; the Spaniards and Italians, contrary to French ideas of military honour, protected themselves by lying prone behind their defenses. Then, while the French made a successful cavalry charge, their ally the duke of Ferrara led his expert artillery round the right flank of the League's infantry and forced them from their now indefensible position. The French and German infantry won the battle convincingly, with the aid of reserves and cavalry; but Gaston, the "thunderbolt of Italy," was killed in a rash charge on a body of retreating Spaniards.

Ravenna surrendered to the French on the following day and was sacked, but was recovered by Julius II without difficulty a few months later, the French army, hindered by the loss of its leader and opposed by a strengthened league, having retreated across the Alps.

This battle is of interest for its use of medieval methods and weapons in conjunction with the foreshadowing of modern, efficient artillery tactics.

See ITALY: History; *see* also references under "Ravenna" in the Index. (J. B. W.-P.)

RAVENNA, EXARCHATE OF, or exarchate of Italy, created by the east Roman emperor Maurice (582–602) as an administrative province to comprise the Byzantine dominions in Italy after the Lombard invasion (*see* ITALY: History); it is first mentioned in 584. Soon after, it came to form part of the new system of "themes" (administrative divisions) established along the frontiers of the empire by Heraclius and his successors. At the beginning of the 7th century the exarchate included Istria, maritime Venetia, Emilia with Ravenna, the Pentapolis, *i.e.*, the coast from Rimini to south of Ancona with the hinterland, Calabria (then the name of the "heel" of Italy), Bruttium (the "toe" of Italy, called Calabria from the late 7th century), Naples, with southern Campania, Rome with northern Campania and southern Tuscany, Perugia, and Liguria.

The territory of Ravenna was also called, in a limited sense, the exarchate of Ravenna. It was under the direct administration

of the exarch, while the other Byzantine possessions in Italy were governed, under his authority, by dukes or *magistri militum*; below them there were tribunes in charge of towns and castles. The internal organization of the exarchate, like that of the themes, was marked by the combination of military and civil powers in the same hands. The exarch, first created as the military governor of Byzantine Italy, thus soon displaced the existing head of the civil administration, the prefect of Italy, whose office seems to have disappeared about the middle of the 7th century. Sicily formed a separate province directly dependent on Constantinople, although the exarch exercised some control over it during that century; Corsica and Sardinia were placed under the exarchate of Carthage.

During the 7th century, the Byzantines suffered further losses; by the middle of the century, Liguria had fallen to the Lombard kings; by the end of it, nearly the whole of Calabria (*i.e.*, the southeast of Italy) had been conquered by the Lombard dukes of Benevento. In 726 a revolt broke out in the exarchate which seriously threatened the Byzantine government; although primarily caused by the iconoclastic policy of Leo III, it was also due to dissatisfaction with the Byzantine administration. After the suppression of the revolt, or after 750, the south Italian dominions were separated from the exarchate and incorporated in the theme of Sicily. The pope, who had played a leading part in the revolt, was gradually becoming the virtual ruler of Rome and its duchy. King Liutprand took advantage of the difficult situation of the Byzantines and extended his power at their expense. After a brief respite, Aistulf continued this policy of conquest; in c. 751 he finally took Ravenna, after its territory (the exarchate in the limited sense) had already been conquered. In northern Italy, Istria and maritime Venetia alone remained Byzantine. Subsequent Frankish intervention made a recovery of the lost dominions impossible; the exarchate in the limited sense and the Pentapolis passed, together with the duchy of Rome, under papal rule.

The Byzantine possessions in southern Italy saw a temporary revival toward the end of the 9th century; in view of the Arab conquest of Sicily, they were then reorganized in the new themes of Longobardia and Calabria. Venice, nominally under Constantinople, became practically independent under its dukes (doges); and this also happened in some of the southern territories, as at Naples. The development toward local and regional autonomy had already started before the downfall of the exarchate, and had undoubtedly contributed to it. Imperial officials became landowners, and local landowners entered the imperial administration. The tribunate tended to become hereditary in the landowning class; the dukes of Venice were elected by the population from the time of the revolt of 726.

RAVENSBURG, a town of West Germany in the *Land* (state) of Baden-Württemberg, Federal Republic of Germany. It lies on the Schussen, 12½ mi. (20 km.) NE of Friedrichshafen by road. Pop. (1961) 31,269. It retains a medieval appearance, with numerous gate- and wall-towers, including the Mehlsack. Outstanding buildings include the 16th-century town hall, the weigh-house (1496), the 14th-century parish church, and the church of St. Jodok (1385). Textiles, paper, and timber are produced, and the town is on the railway from Friedrichshafen to Ulm. The Rutenfest, a children's festival dating from the 17th century, is held. The town grew up around the ancestral castle of the Guelphs (where Henry the Lion was born) on the Veitsburg. In 1180 it passed to the Hohenstaufens. From 1276 to 1802 it was a free city of the empire. During the 14th and 15th centuries an important trading company flourished there.

RAVENSCHROFT, THOMAS (c. 1583–c. 1633). English composer, chiefly remembered for his social songs and his collection of psalm settings, was born perhaps in Sussex about 1583. He became a chorister of St. Paul's Cathedral, London. In 1607 he took his B. Mus. at Cambridge. From 1618 to 1622 he was music master at Christ's Hospital. He died about 1633.

Ravenscroft's *Whole Booke of Psalmes* (1621), comprising over

100 metrical psalm tunes, proved extremely popular. Ravenscroft himself harmonized about half the melodies, commissioning or compiling the rest from other composers. Several of his versions are still in use.

His secular collections are full of interest for the sociologist or historian of popular music. *Pammelia* (1609), containing 100 catches and rounds, was the first anthology of its kind; *Deuteromelia* (1609) has 31 items, including "Three blind mice"; *Melismata* (1611) has 23 songs for the "court, city, and country humours"; and his theoretical work, the *Briefe Discourse* (1614), appends further characteristic pieces. Ravenscroft aimed cunningly to please a middle-class lay public very different from the educated élite who enjoyed the madrigal or the air (*q.v.*; *ayre*).

See W. H. Havergal (ed.), *A Reprint of All the Tunes in Ravenscroft's Book* (1845); P. Warlock (ed.), *Thomas Ravenscroft: Pammelia and Other Rounds and Catches* (1928). (B. L. Tr.)

RAVI, one of the "five rivers" of the Punjab (*q.v.*), rises in the Himalayas in the Kulu subdivision of Kangra District, Punjab (India), and flows through Chamba, the isolated northern division of Himachal Pradesh. Turning southwest it briefly enters Jammu and Kashmir and the Gurdaspur District (Punjab, India), then for nearly 100 mi. (160 km.) forms the India-Pakistan frontier before entering West Pakistan about 15 mi. (24 km.) NE of Lahore. Lahore itself is not sited on the river but lies a mile or two to the south. Flowing west-southwest across the Punjab plains, the Ravi finally falls into the Chenab about 10 mi. (16 km.) S of Ahmadpur after a course of about 450 mi. (724 km.). Its water is used for the irrigation of the Bari Doab (interfluvium), the country between the Ravi and the Sutlej. The Upper Bari Doab Canal (completed 1878-79), with headworks at Madhopur on the Indian side of the frontier, serves about 1,177,000 ac. (476,300 ha.) of the Upper Bari Doab around Amritsar, mainly in India. Some of the distributory canals, however, enter Pakistan, and until the waters agreement of 1960 the alleged withholding of irrigation water by India was a source of constant irritation to Pakistan. The Lower Bari Doab Canal (completed 1917), with headworks also on the left bank of the Ravi at Balloki, irrigates about 345,000 ac. and lies entirely in Pakistan. The waters of the Ravi are supplemented for the irrigation of the Lower Doab by canals leading from the Jhelum and the upper Chenab. The Sidhnai Canal, beginning about 10 mi. above the Chenab junction, was frequently dry in winter until the construction of the Haveli Canal (1939), delivering water to the Ravi from the Trimmu Barrage at the Chenab-Jhelum confluence. (T. HER.; L. D. S.)

RAWALPINDI, a town, cantonment, district, and division of West Pakistan. The town, interim capital of Pakistan from 1959, and headquarters of the district and division, lies on the Grand Trunk Road, 108 mi. (174 km.) ESE of Peshawar and 179 mi. (288 km.) NW of Lahore. Pop. (1961) 340,175, including the cantonment. Rawalpindi ("village of Rawals") occupies the site of an old village inhabited by Rawals, a tribe of yogis (ascetics). Gen. Sir Alexander Cunningham, director general of the Indian Archaeological Survey (1870-85), identified certain ruins on the site of the cantonment with the ancient city of Gajipur or Gajnipur, the capital of the Bhatti tribe in the centuries preceding the Christian era. Also known as Fatehpur Baori, it was destroyed during one of the Mughal invasions. It was said to have been restored by Jhanda Khan, a Gakhar chief, and named Pindi or Rawalpindi from the once flourishing village Rawal, a few miles north of the town on the road to Murree. Sardar Milka Singh, a Sikh adventurer, occupied it in 1765 and invited traders from Jhelum and Shahpur districts to settle there, the town thereafter growing rapidly in importance. Early in the 19th century it became for a time the refuge of Shah Shuja, the exiled amir of Kabul, and his brother Shah Zaman. At Rawalpindi on March 14, 1849, the Sikh army under Chattar Singh and Sher Singh finally laid down their arms after the Battle of Gujrat. During British rule Rawalpindi became a cantonment of considerable size and the headquarters of a division. After independence in 1947 it became the headquarters of the Pakistan Army.

The Leh Nullah (watercourse) separates the city from the cantonment and the civil station. A satellite town has been built

GUNTHER REITZ—PIX FROM PUBLIX

TERRACED HILLSIDES NEAR MURREE IN THE RAWALPINDI DISTRICT

on the Murree Road. Ayub National Park and Liaquat Gardens are the chief places of recreation and there are several notable old buildings. The city has three colleges affiliated with the University of the Punjab, a polytechnic, a police training institute, and an armed forces medical college.

Industrial enterprises include the locomotive works of the Pakistan Western Railway, gasworks, an oil refinery, an iron foundry, a tent factory, a brewery, and cotton and silk textile and hosiery mills. The making of marble chips is an important cottage industry. An annual horse fair is held in April. The airport is in the Chaklala Cantonment area. The town is the starting point of the road to the hill station of Murree and of the route into Kashmir.

RAWALPINDI DISTRICT (area 2,022 sq.mi. [5,237 sq.km.]; pop. [1961] 1,137,085) forms a compact square in the north of the division, with the highland tract called the Murree Hills jutting from its northeastern corner and the Kahuta Hills bordering it on the east. To the southwest stretches the rough undulating Potwar Plateau (1,800 ft. [549 m.]) intersected by many torrents. The northern part is drained by the Soan (Sohan) River and the southern by the Kanshi, while the Jhelum flows on the east. The climate is on the whole healthy, with long cold winters and short hot summers. Murree is under snow for about two months in the year. The rainfall is good (Rawalpindi 36 in. [914 mm.], the hills 53 in. [1,346 mm.]). Both the summer monsoon and winter rains are characteristic. Agriculture depends almost entirely on rainfall. Wheat and barley are the chief crops of the spring and millets of the autumn harvest.

The district in ancient times formed part of Gandhara and was included in the Persian Empire of the Achaemenids. It possesses several sites of archaeological interest including that of the ancient city of Taxila which has been identified with ruins near Shahdheri (Shah-dheri), 20 mi. (32 km.) NW of Rawalpindi. The Buddhist remains of Mankial (Mankiala) lie 14 mi. (23 km.) S of Rawalpindi and 3 mi. (5 km.) from Riwayat, another place of antiquity containing Neolithic burial places and the mausoleum of Sultan Sarang (d. A.D. 1543).

Islamabad, the site of the new capital of Pakistan, lies about 3 mi. (5 km.) NE of Rawalpindi on the road to Murree. The name reflects the country's emphasis on peace. The site is roughly a trapezoid and together with its environs covers an area of 250 sq.mi. (648 sq.km.). Its altitude ranges from 1,500 to 2,000 ft. (450 to 600 m.).

The Rawal Dam, about 9 mi. (14 km.) from Rawalpindi, on the Kurang River (which joins the Soan southeast of the town), was completed in 1961-62 and designed to irrigate 10,000 ac. (4,000 ha.) of land and to provide the Rawalpindi and Islamabad areas with 14,000,000 gal. of water daily.

RAWALPINDI Division occupies the north of West Pakistan and comprises the districts of Rawalpindi, Jhelum, Gujrat, and Attock. Area 11,206 sq.mi. (29,024 sq.km.). Pop. (1961) 3,979,139. It is mostly a submontane region, intersected by numerous nullahs and the adjacent parts of the Himalayas. The Salt Range divides it into two parts. Gujrat on the southeast of the Salt Range is largely a plain, while the other three districts extend mainly over the Potwar Plateau, except for a small hilly area in the north. Wheat and millet are the chief crops. The headquarters of the districts are linked by the Grand Trunk Road and by the Pakistan Western Railway. (K. S. Ad.)

RAWLINS, a city of south central Wyoming, U.S., 163 mi. NW of Cheyenne; the seat of Carbon County. It was founded in 1868 when the Union Pacific Railway arrived. The town was first named Rawlins Springs for U.S. Army Gen. John A. Rawlins, who had discovered a pleasant spring of fresh water at that point in 1867, but the word "Springs" was soon dropped. Rawlins was incorporated as a city in 1886.

The Union Pacific Railway Company has always been a principal employer. Quite early Rawlins also became known as a cattle and sheep centre. It is also a centre for antelope hunting and in the 1950s became an important shipping point for uranium ore from the Gas Hills area to the north. The state penitentiary is located at the north edge of Rawlins and an oil refinery is 6 mi. away at Sinclair. For comparative population figures see table in WYOMING: Population. (T. A. L.N.)

RAWLINSON, SIR HENRY CRESWICKE (1810–1895), English soldier and orientalist who deciphered the Bisitun (q.v.) rock inscription of Darius I the Great of Persia, was born at Chadlington, Oxfordshire, on April 11, 1810. In 1827 he went to India as an East India Company cadet and after six years was sent to Persia with other British officers to reorganize the shah's army. In Persia he became interested in the hitherto undeciphered cuneiform writing. In two years he transcribed as much as he was able of the great trilingual cuneiform inscription at Bisitun but friction between Persia and Britain ended in the departure of the British officers. He became political agent at Kandahar in 1840. Then at his own request, he was sent as political agent to Turkish Arabia and as consul at Baghdad where he made a complete transcript of the Bisitun inscription, which he deciphered and interpreted (1846). During two years' leave in England (1849–51) Rawlinson disposed of his valuable collection of Babylonian, Sabaean, and Sasanian antiquities to the trustees of the British Museum, who made him a grant to enable him to carry on the Assyrian and Babylonian excavations initiated by Sir Austen Layard. In 1851 he returned to Baghdad and in the following years collected many valuable sculptures for the museum. On resigning his post with the East India Company in 1855 he was knighted and appointed a crown director of the company. The remaining 40 years of his life were spent mainly in London. First appointed to the India Council in 1858 he was reappointed in 1868 and continued to serve on the Council until his death in London on March 5, 1895. He sat in Parliament for the Reigate Division (1858) and for the Frome Division of Somerset (1865–68). He was created a baronet in 1891.

His published works include *The Persian Cuneiform Inscription at Behistun* (1846–51); *Outline of the History of Assyria* (1852); *A Commentary on the Cuneiform Inscriptions of Babylonia and Assyria* (1850); *Notes on the Early History of Babylonia* (1854); *England and Russia in the East* (1875). He contributed to the *Encyclopædia Britannica* (9th ed.), including the articles on Baghdad, Euphrates, and Kurdistan.

BIBLIOGRAPHY.—G. Rawlinson, *A Memoir of Henry Creswicke Rawlinson* (1898); E. A. T. W. Budge, *The Rise and Progress of Assyriology* (1925); S. Lloyd, *Foundations in the Dust* (1947, reprinted 1955).

RAWLINSON, HENRY SEYMOUR RAWLINSON, 1ST BARON (1864–1925). British general and commander in chief in India. was born at Trent manor, Dorset, on Feb. 20, 1864, son of Sir Henry Creswicke Rawlinson (q.v.). Joining the King's Royal Rifles in 1884, he took part in the Burma (1886–87) and Nile (1898) campaigns, having in 1892 obtained a transfer to the Coldstream Guards. He served with distinction throughout the South

African War (1899–1902) and was commandant of the staff college at Camberley (1903–06). After the outbreak of World War I he took command of IV Corps in 1914 and with it fought in the first Battle of Ypres and in 1915 at Neuve Chapelle and Loos. Early in 1916 he created and commanded the 4th Army with which he fought the Battle of the Somme. He was promoted general in January 1917. For a few weeks early in 1918 he was the British military representative on the supreme war council at Versailles, but in April he resumed command of the 4th Army. On Aug. 8, he attacked near Amiens and gained a great victory, the first of several which led to the general advance of the allied armies and the armistice of November. He was created Baron Rawlinson of Trent in August 1919 and from August to October he carried out the withdrawal of the allied forces from Archangel and Murmansk in north Russia. He then commanded for a year at Aldershot, before going to Delhi in November 1920 as commander in chief in India, where he reorganized the Indian Army. He died at Delhi on March 28, 1925.

See Sir F. B. Maurice, *Life of General Lord Rawlinson of Trent . . . from His Journals and Letters* (1928). (R. G. TH.)

RAWTENSTALL, a municipal borough (1891) of Lancashire, Eng., lies in the ancient Forest of Rossendale, 17 mi. (27 km.) N of Manchester on the trunk road from Manchester to Burnley. Pop. (1961) 23,890. First known to have been mentioned in a survey of the hundred of Blackburn (1323), Rawtenstall became an industrial area early in the 19th century. Its older industries of woolen, cotton, felt, and slipper manufacture are now augmented by box-making, quilting, rubber, and chemical productions. There is an art gallery and museum with a collection of footwear, and a college of further education.

RAY (WRAY), JOHN (1627–1705), English naturalist, famous for his systems of natural classification, was born at Black Notley, Essex, on Nov. 29, 1627. He graduated B.A. from Cambridge in 1647/48 and in 1649 secured a fellowship at Trinity college, obtaining his M.A. degree in 1651. He resigned his fellowship in 1662 because he could not subscribe to the Act of Uniformity. He devoted himself to science, aided through the generosity of Francis Willughby, with whom Ray agreed to work on a survey and classification of plants and animals. They made several botanical tours in Britain and, from 1663 to 1666, traveled in Europe. In 1667 Ray was elected a fellow of the Royal society. Willughby died in 1672, leaving Ray an annuity for life. Subsequently Ray published (1673) an account of their European travels. Ray died at Black Notley on Jan. 17, 1705.

Ray's system of plant classification, which greatly influenced the development of systematic botany, appeared in the *Methodus plantarum nova* (1682) and, in final form, in *Methodus plantarum emendata* (1703). Ray was the first to distinguish (1682) the divisions that he later (1703) called "Monocotyledones" and "Dicotyledones" (from cotyledon, a seed leaf; see PLANTS AND PLANT SCIENCE; ANGIOSPERMS), both fundamental in modern classifications though altered in content from Ray's concept. His *Catalogus plantarum circa Cantabrigium* (1660) was the first flora of Cambridgeshire, and his *Catalogus plantarum Angliae* (1670; 2nd ed., 1677) and *Synopsis methodica stirpium Britannicarum* (1690; 2nd ed., 1696), the former arranged alphabetically and the latter according to his classification system, were the first floras of Britain. The *Historia plantarum* (1686–1704) described all known plants and arranged them in his system. The book's introductory essays, surveying botanical knowledge, formed the most complete treatise that had appeared on plants in general. Ray was the first to attempt to define what constitutes species.

Ray's zoological works were characterized by Georges Cuvier as "the basis of all modern zoology." The "foundation of scientific ornithology" (A. Newton) was laid in the *Francisci Willughbeii . . . ornithologiae libri tres* (1676), amplified and edited by Ray from the incomplete manuscript left by Willughby. The classification, which was for the most part followed later by Linnaeus, appears to have been of Ray's devising. The bases for the natural classification of fishes were laid in *Francisci Willughbeii . . . historia piscium* (1686), wherein the major share of the work

was apparently that of Ray. This work greatly influenced Peter Artedi, whose arrangement of fishes was adopted by Linnaeus. The earliest classification of animals based upon anatomical characters was that in Ray's *Synopsis methodica animalium* (1693). He maintained Aristotle's great divisions, animals with blood (*i.e.*, vertebrates) and those "without" blood (*i.e.*, invertebrates). In the former he laid the basis for Linnaeus' first four classes. Ray also issued a preliminary *Methodus insectorum* in 1705 and his *Historia insectorum*, incomplete when he died, was published in 1713 as it stood and without figures. Ray's system of insects, following Jan Swammerdam, was based upon metamorphosis (*q.v.*).

Ray also wrote *A Collection of English Proverbs* (1670; reissued 1855 and 1875) and *A Collection of English Words* (1674; reissued 1874).

The Ray society, for the publication of works on natural history, was founded in his honour in 1844.

BIBLIOGRAPHY.—C. E. Raven, *John Ray*, 2nd ed. (1950); G. Keynes, *John Ray, a Bibliography* (1951); E. Lankester (ed.), *Memorials of John Ray* (1846), with a listing of Ray's works. (J. W. Tr.)

RAY (RAYY or RAI), formerly one of the great cities of Iran, the ancient RAGHA, Latin RHAGES. Its site is in Teheran *ostan* (province) 5½ mi. SSE of Teheran City. The expedition of the Boston and Pennsylvania museums disclosed a prehistoric settlement on the site dating from the 3rd millennium B.C. Ray is mentioned in the Avesta as a sacred place and it is also mentioned in the Book of Tobit (*q.v.*). The city was well known to classical authors, who frequently referred to it. It was less important in Sasanian times; there was a considerable Christian settlement there, and it became the see of a Nestorian metropolitan. Ray was captured by the Muslim Arabs in 641. Before al-Mahdi became caliph, he was for a time governor of Ray; it was there, in about 766, that his son Harun al-Rashid was born. Under al-Mahdi's rule, the city rapidly regained its importance, being rivaled in western Asia only by Damascus and Baghdad. It is said to have covered 25 sq.mi. (65 sq.km.) and to have had a population of no less than 8,000,000, but this is undoubtedly a gross exaggeration. The Arab geographer Yaqut refers to Ray as a city of extraordinary beauty, built largely of fired brick and brilliantly ornamented with blue faience; but he also speaks of the dark and crooked streets and lanes which made it a formidable obstacle to invaders. It continued to be a city of political, commercial, and artistic importance under the Seljuks. In the 12th century it was tormented and greatly weakened by the fury of rival religious sects. In 1220 it was captured and almost entirely destroyed by the Mongols, most of the inhabitants being massacred. Many of those who survived moved to nearby Teheran, leaving only a handful in the old city, which soon fell completely into ruin.

Ray was famous for its decorated silks of an unsurpassed *finesse* and artistic perfection, and also for its ceramics. Only two architectural monuments survive; these are the tower of Toghrul, or Tughril, (1139) and the so-called Naqqara-khana, a partially ruined tower, also of the Seljuk period, on the hillside overlooking the site of the city. The small town of Shah 'Abdul 'Azim which adjoins the ruins has been renamed Rey.

RAY, a common name loosely applied to any of the numerous cartilaginous fishes (class Chondrichthyes) of the order Batoidae, distinguished from the related modern sharks by a flattened body, which has the five gill openings and the mouth generally located entirely on the undersurface, and by the greatly enlarged pectoral fins, which extend forward along the sides of the head above the gill openings. Rays are well fitted by their structure for life at the bottom of the sea. On the upper surface of the head, behind the eyes, are large holes leading to the pharynx; these are termed spiracles and serve for the intake of water for respiration. Most bear young live, but the skates (family Rajidae) have eggs enclosed in oblong horny cases similar to those of dogfishes. As in the sharks, the males have the posterior edges of the pelvic fins modified to form copulatory organs. For

a detailed discussion of the anatomy and relationships in cartilaginous fishes see CHONDROCHTHYES.

The rays (Batoidei) may be broken down into the following special groups: electric rays (family Torpedinidae), guitarfishes (Rhinochordidae), sawfishes (Pristidae), skates (Rajidae), stingrays (Dasyatidae), eagle rays (Myliobatidae), mantas, including the devil rays (Mobulidae).

Electric Rays.—The electric rays form an isolated family distinguished by large paired electric organs formed of vertical hexagonal columns, between the pectoral fins and the head, and capable of giving powerful shocks either for defensive purposes or to kill prey. The electric rays have a smooth and naked skin; the head and trunk with the pectoral fins form a circular disc; the tail is short and stout. About 20 species are known from warm seas, some reaching a weight of 200 lb. One representative species is the torpedo (*Torpedo nobiliana*), which occurs from North Carolina to Nova Scotia and from tropical west Africa to Scotland. Another is *Torpedo californica*, which occurs along the Pacific coast of the United States from central California northward.

Nonelectric Rays.—The other rays, without electric organs, generally have a rough skin, often bearing strong spines. The most sharklike are the guitarfishes (Rhinochordidae) of which about 20 species are known from tropical and subtropical seas; in most of them the pectoral fins are relatively small and the trunk passes gradually into the tail. The sawfishes, or sawrays (*Pristis*), differ from them in that the snout is produced into a long blade armed with a series of strong teeth on each side; five species are known from warm seas, frequenting sandy shores and estuaries.

The American sawfish (*Pristis pectinatus*) is common in the Gulf of Mexico, about the West Indies and occasionally is found on the Atlantic coast as far north as New Jersey. Small ones are excellent food. Some attain a length of 20 ft.; such large specimens are dangerous, the saw being a formidable weapon.

In the skates the large pectoral fins extend to the snout and backward stopping abruptly at the base of the slender tail. Numerous species of the cosmopolitan genus *Raja* are known, some living at considerable depths; some species reach a weight of 500 lb. These rays swim by undulating or flapping movements of the pectoral fins; their teeth are small and blunt in some species, pointed in others. Skates have two small dorsal fins on the rear part of the tail; they lack a distinct tail fin and also the long, slender recumbent barbed spine that characterizes the tail of stingrays. Their food consists of mollusks, crustaceans and fishes. Skates produce large, oblong eggs with dark, leathery shells having a tendril at each corner by which they become fastened to seaweed or other objects. The largest western Atlantic species is the Barndoor skate (*Raja laevis*), which is said to reach a length of six feet. Its European counterpart is *R. batis*. A Pacific American species, the California skate (*Raja inornata*), which occurs from San Diego to the Strait of Juan de Fuca, is probably the principal species of commerce in the northeastern Pacific. Around 80,000 tons of skates are caught annually in trawls, traps and beach seines and on hook and line. The largest quantities are landed in Japan, France, Great Britain and Spain. The pectoral fins are cut off and used as food.

The remaining rays are collectively termed "whip-tailed," the tail being long and slender and usually having a barbed spine connected with a poison gland; this spine is capable of inflicting serious wounds and is a dangerous weapon when the tail is lashed.

BY COURTESY OF MIAMI SEAQUARIUM
UNDERSIDE OF SOUTHERN STINGRAY (DASYATIS AMERICANA), FAMILY DASYATIDAE

All the whip-tailed rays are inhabitants of warm seas, except a few kinds of stingray in the rivers of South America. In the stingrays (*Dasyatis*, etc.), as in most of the rays previously described, the teeth are numerous, small and blunt; in the eagle rays (*Myliobatis*) the teeth are relatively few in number, hexagonal, forming a flat pavement, and in the spotted eagle rays (*Aetobatus*) are reduced to a single series of broad flat teeth used to crush the shells of mollusks.

The largest rays are the devil rays, *Manta* and *Mobula*, which may measure 20 ft. across the disc. Unlike other whip-tailed rays, they lack the tail spine. The anterior ends of the pectoral fins are free and project forward; when rolled up, the edges look like a pair of horns, but when unrolled, they meet below the mouth to form a scoop. Devil rays have been observed pursuing small fishes and scooping them into their mouths. (C. T. R.; L. A. Wd.)

RAYAH (meaning "flock" in Arabic), though it was the name originally given to all the subjects of a Muslim ruler, later was limited to those non-Muslim subjects who paid the poll tax. Within the Ottoman Empire the rayahs were grouped into five communities (*milletler*): the Greek Orthodox, the Gregorian Armenian, the Catholic Armenian, the Latin Christian, and the Jewish. Of these five communities, only the Orthodox was subject to *devshirme* (tribute of children; see JANIZARIES). The individual rayah had no direct relations with his Muslim ruler but was subject to and represented and taxed by his own religious leader (*millet-bashi*). The origin of this system lay in the custom of the Roman, Byzantine, and caliphate empires of allowing self-government to subject communities. The system had some disadvantages, but it ensured the minority groups a large degree of liberty in matters of religion, property, and communal organization.

(A. D. A.)

RAYBURN, SAM (SAMUEL TALIAFERRO RAYBURN) (1882–1961), U.S. political leader who served as speaker of the U.S. House of Representatives for 17 years, was born in Roane County, Tenn., Jan. 6, 1882. His family, of predominantly Scottish origin, moved to Texas in 1887, and there Rayburn grew up on a 40-ac. farm. He worked his way through East Texas State College at Commerce, taught school, and became a lawyer. He served in the Texas House of Representatives for six years (1907–13) and in 1911 was elected speaker. In 1912 he was elected to the U.S. House of Representatives and served there continuously for 48 years and 8 months, a record tenure. He was elected to Congress 25 consecutive times.

Energetic, studious, ambitious, and affable, Rayburn quickly became influential behind the scenes in government and in party politics. As chairman of the powerful Congressional Committee on Interstate and Foreign Commerce (1931–37), he was a major architect of the New Deal. As a member of the House of Representatives he was co-author of six important laws—Railroad Holding Company Act, "Truth-in-Securities" Act, Securities Exchange Act, Federal Communications Act, Rural Electrification Act, and the most bitterly contested of all New Deal laws, the Public Utility Holding Company Act.

Rayburn was elected Democratic leader of the House of Representatives in 1937 and became speaker of the House on Sept. 16, 1940. He held the latter office for 17 years, exceeding by a wide margin the record set by Henry Clay in the first quarter of the 19th century. Noted for his tart common sense, honesty, and unflagging patriotism, he was a trusted adviser to Presidents Roosevelt, Truman, Eisenhower, and Kennedy. A dedicated party man who described himself as a Democrat "without prefix, without suffix, and without apology," Rayburn was often called "Mr. Democrat." He was permanent chairman of the Democratic National Conventions in 1948, 1952, and 1956. After winning the battle in 1961 to enlarge the House Committee on Rules—the hardest internal House struggle in 50 years—Rayburn's health failed quickly. Before Congress adjourned, he went home to Bonham, Tex., where he died on Nov. 16, 1961. (L. B. J.)

See C. D. Dorough, *Mr. Sam* (1962).

RAYLEIGH, JOHN WILLIAM STRUTT, 3RD BARON (1842–1919), British physicist, was awarded the Nobel Prize for Physics in 1904 for his discovery (1894) of the noble elementary

gas, argon, in collaboration with Sir William Ramsay. He was born near Maldon, Essex, on Nov. 12, 1842, and educated at Trinity College, Cambridge, where he graduated senior wrangler (1865). As successor to James Clerk Maxwell he was head of the Cavendish Laboratory at Cambridge from 1879 to 1884, and in 1887 he became professor of natural philosophy in the Royal Institution of Great Britain. Elected (1873) a fellow of the Royal Society, he was president from 1905 to 1908. He was an original recipient of the order of merit (1902) and a privy councillor (1905). His researches ranged over almost the whole field of physics, including sound, wave theory, optics, colour vision, electrodynamics, electromagnetism, the scattering of light, hydrodynamics, the flow of liquids, capillarity, viscosity, the density of gases, photography, and elasticity as well as electrical measurements and standards. His researches on sound were embodied in his *Theory of Sound*, two volumes (1877–78, 2nd ed. 1937, reprinted 1956), and his other extensive studies in physics appeared in his *Scientific Papers*, six volumes (1899–1920). He died on June 30, 1919, at Witham, Essex.

RAYMOND, SAINT, OF PEÑAFORT (c. 1185–1275), Spanish Dominican friar, compiler of one of the most important pieces of medieval legislation, the *Decretals of Gregory IX*, which, though later supplemented by other papal enactments, remained substantially in force in the Roman Catholic Church until the new codification of 1917. Raymond was born at the castle of Peñafort (Penyafort) near Barcelona and received his early education in the cathedral school of that city. As a young priest he went to study canon law at Bologna and subsequently taught there from 1218 to 1221. During this period he wrote unpublished glosses on the *Decretum* of Gratian (*q.v.*) and a general treatise (*Summa*) on canon law which he left uncompleted. After his return to Barcelona early in 1222 he entered, on Good Friday, the Dominican Order at the monastery of St. Catherine's. Between 1222 and 1226 he wrote a manual of canon law for confessors, *Summa de casibus poenitentiae*, which was to become one of the most widely used books of its kind during the later Middle Ages. In 1229 he served as chaplain to the papal legate in Spain, Cardinal John of Abbeville, and thereafter was called to Rome by Pope Gregory IX, who appointed him to the college of *poenitentarii*, the papal chaplains in charge of examining cases of conscience reserved or otherwise referred to the Holy See.

In 1230 the pope commissioned Raymond to recast into a single codification the papal statutes and rulings on points of canon law (*litterae decretales*) which had been issued since the appearance of Gratian's *Decretum* in mid-12th century and were by this time circulating in five different, poorly coordinated collections. Raymond's compilation, the *Decretals of Gregory IX*, was formally promulgated by the pope on Sept. 5, 1234. In 1235 Raymond revised and reissued his *Summa de casibus*, with an added part on the law of matrimony.

The next year he returned to Spain and in 1238 was elected master general of the Dominican Order but resigned after only two years in office. A revision of the constitutions of the order remains the chief monument of this brief tenure. The rest of Raymond's life was in part filled by various papal commissions but mainly by missionary interests. Already in 1235 he had written a set of instructions for the missions in Tunisia, and he may have had a hand in the papal approval (1235) of the Mercedarians, founded in Spain for the ransoming of Christian slaves in Muslim lands. Later he organized schools of Arabic and Hebrew studies for missionaries in Tunis and in Murcia (c. 1255), and it was at his request that St. Thomas Aquinas undertook to write the *Summa contra gentiles*. Raymond died on Jan. 5, 1275. He was canonized as saint in 1601 (feast on Jan. 23).

RAYMOND OF POITIERS (1099-1149), prince of Antioch from 1136, was the younger son of William VII, count of Poitiers (William IX as duke of Aquitaine), and Philippa of Toulouse. In 1135 King Fulk of Jerusalem, regent for the infant heiress Constance of Antioch, sent envoys to offer her in marriage to Raymond, who was then at the court of Henry I of England. Arriving in Antioch in spring 1136, Raymond married Constance and so became prince. His wife's mother, Alice of Jerusalem, who had herself hoped to marry him, thereafter tried to undermine his authority.

In 1137 the Byzantine emperor John II Comnenus, who claimed suzerainty over Antioch, obliged Raymond to do homage and even to promise to cede the principality as soon as John should have won new territory for him in the East, where the *atabeg* Zangi (Imad-al-Din) of Mosul, already in possession of Aleppo, was encroaching on the principality's frontiers. John and Raymond, however, failed to win any such territory in their campaign of 1138; and though John made a solemn entry into Antioch, Raymond remained in control, campaigning against the Muslims and intriguing against the Latin patriarch, Radulf. After Zangi's conquest of Edessa (1144) had exposed Antioch to attack from the northeast also, Raymond's position was weakened, and he visited Constantinople in 1145 to conciliate John II's successor, Manuel I. His relations with his niece, Eleanor (*q.v.*) of Aquitaine, who visited Antioch in 1148 with her husband Louis VII of France, gave rise to scandalous rumours. On June 28, 1149, Raymond was killed near Inab in battle against Zangi's successor, Nureddin. *See* CRUSADES.

RAYMOND IV (1041 or 1042-1105), count of Toulouse, also called **RAYMOND OF SAINT-GILLES** (from the abbey which formed part of his original fief), was the second son of Count Pons and his consort Almodis. His first marriage, to his cousin, the heiress of Venaissin, together with rights inherited from his grandmother Emma, enabled him to bear the title of marquis of Provence (*see* PROVENCE), but this marriage was condemned by the church, and his wife disappeared, after giving him a son, Bertrand. He married, secondly, Matilda, daughter of Roger I of Sicily (*c.* 1080); and, thirdly, Elvira, a bastard daughter of Alfonso VI of Castile (before 1094), possibly after campaigns against the Moors in Spain. On the death of his elder brother William IV (*c.* 1093), he succeeded to the whole countship of Toulouse.

Through various measures and donations, Raymond had already shown himself a pious leader of the papacy's reform movement in the church. Pope Urban II had probably secured his agreement before beginning his campaign for the First Crusade, and Raymond was the first of the princes of Western Europe to take the cross. He left France in October 1096 and made his way to Constantinople through northern Italy and Dalmatia and along the old Via Egnatia across the Balkans. His first contacts with the Byzantine emperor Alexius I were rather rough, and he refused to do formal homage to him. A compromise was reached, however, with a mutual oath of help and Raymond's undertaking to respect Byzantine territorial rights. Raymond was to be the most conscientious partisan of the Greek-Latin alliance, sometimes to his disadvantage.

Raymond fell ill in summer 1097, while crossing the deserts of Asia Minor. In October, on a rumour that the Turks had abandoned Antioch, he sent a reconnaissance party, which his rivals later represented as an indication of his personal designs on that city. He played his part in the siege of Antioch; and when the crusaders were in turn besieged there by Kerbogha of Mosul, a great revival of religious activity among his troops culminated in the discovery of the Holy Lance by a Provençal. This miracle stimulated the crusaders to defeat Kerbogha; but it was also held to be a product of gross intrigues by Raymond and a further proof of his ambitions. Raymond seems to have insisted that Antioch should be restored to the Byzantine emperor, whereas Bohemund I (*q.v.*) claimed it for himself as a reward for his role in its capture. Eventually Bohemund expelled Raymond's garrison from Antioch and remained in possession of it.

From the fall of Antioch onward Raymond appears as the true

leader of the Crusade, the organizer of the march on Jerusalem. Some of his actions aroused criticism, for instance his siege of Arqa (Arqah, northeast of Tripoli; spring of 1099); but he was a successful leader, and he finally helped in the storming of Jerusalem (July 1099). He seems to have refused the royal crown, which was then given to Godfrey of Bouillon. He quarreled with Godfrey, but still helped him to repel the attack launched by the Fatimids of Egypt, which was crushed at Ascalon. (*See* further CRUSADES.)

Raymond may have taken a vow never to return to his lands in southern France. Yet he alone among the leaders of the Crusade had conquered no principality in Syria. His last years in the Orient were occupied with a voyage to Constantinople (perhaps to secure Alexius I's approval for projected conquests); with a new and ill-fated expedition of crusaders; with quarrels with Tancred, regent of Antioch during Bohemund's captivity; and with efforts to create a countship around Tripoli, which his heirs were to bring to success. He died on Feb. 28, 1105, in the castle of Mons Peregrinus (Mont Pèlerin), built by him near Tripoli. Of all leaders of the Crusade, Raymond was probably the most faithful both to Urban II's original plans and to the alliance with Alexius, which proved necessary. He was given the title of "most excellent chief of the Christian Militia." Yet his merits were obscured by chroniclers supporting his rivals and also by the rather unintelligent account of events given by his own chaplain, Raymond of Aguilers, in his *Historia Francorum qui ceperunt Iherusalem*.

See John H. and Laurita Hill, *Raymond IV de Saint-Gilles, comte de Toulouse* (1959; Eng. trans., 1962); J. Richard, *Le Comté de Tripoli sous la dynastie toulousaine* (1945). (P. Wo.)

RAYMOND VI (1156-1222), count of Toulouse from 1194, was the son of Count Raymond V by his wife Constance, sister of Louis VII of France. He was five times married: first, in 1172, to Ermessinde, heiress of the countship of Melgueil (*d.* 1176); second, at an unknown date, to Beatrix, sister of Roger II, viscount of Béziers; third, about 1193 (presumably after repudiating Beatrix), to Burgundia of Cyprus, daughter of the future king Amalric II of Jerusalem, despite the consanguinity for which he later repudiated her; fourth, in 1196, to Joan (*d.* 1199), daughter of Richard I of England and the mother of his son, the future Raymond VII (*q.v.*); and fifth, in 1200 or 1204, to Leonora, sister of Peter II of Aragon. His two last marriages, contracted after his accession to the countship of Toulouse on his father's death (1194), allied him to dynasties which had been his father's great opponents. Joan brought him Agenais as her dowry, while Richard I at the same time restored Quercy from Aquitaine to Toulouse; and as Leonora's husband he was later able to appeal for Aragonese help during the Albigensian Crusade.

The Albigensian Crusade, that is, the holy war against the heretical Cathari (*q.v.*) of Languedoc, was the critical event which Raymond had to face. Before it began he had already been excommunicated, from 1195 to 1198, for an enterprise against the abbey of Saint-Gilles. Unlike his father, he adopted an attitude of indifference toward the heresy spreading over his lands. Pope Innocent III's legate, Peter de Castelnau, urged him in vain, from 1205, to stamp it out and even excommunicated him in 1207. An angry interview took place between the two men; and on Jan. 15, 1208, the legate was murdered, supposedly by one of the count's followers. Innocent III then launched the Crusade.

Raymond at first tried to halt the onslaught by making public amends to the church in a ceremony at Saint-Gilles (June 1209). Next, to everyone's surprise, he took the cross himself. The crusaders, however, after establishing Simon de Montfort as viscount of Béziers and Carcassonne in the place of Raymond Roger Trencavel, turned their attack farther westward. Raymond VI then saw himself obliged to oppose them. The people of Toulouse refused to expel him and underwent the first siege with him (June 1211); but he and Peter II of Aragon were disastrously defeated in September 1213, at the Battle of Muret.

Though he offered to abdicate in favour of his son, the Lateran Council of 1215 deprived Raymond VI of his countship and bestowed it on Simon de Montfort. It also stipulated that Raymond

should live outside his lands, a portion of which was, however, reserved for his young son. Raymond VI did not accept the sentence. While his son was besieging Simon's garrison in Beaucaire, Raymond VI made his way to Aragon and raised a small force there. He then returned to occupy Toulouse (September 1217); and Simon, besieging the city, was killed outside it (June 1218). Raymond had recovered the major part of his lands when he suddenly died, in August 1222. His son could not obtain Christian burial for him. (P. Wo.)

RAYMOND VII (1197–1249), count of Toulouse from 1222, was born at Beaucaire in July 1197, the son of Count Raymond VI (q.v.) by his fourth wife, Joan of England. He was present in Rome in 1215, when the Lateran Council reserved for him his family's inheritance in Provence, though it dispossessed his father. Received with delight in Provence, he was able to contribute notably to his father's restoration: his attack on Beaucaire led to the capitulation of Simon de Montfort's garrison there (1216); he marched to his father's help in besieged Toulouse; and after Simon's death he reconquered Agenais and Quercy, won a battle near Baziège against supporters of Amaury de Montfort, and was the soul of Toulouse's resistance when it was again besieged in 1219. Succeeding his father in 1222, he obtained a truce from Amaury in 1223. At a council in Montpellier (1224) he declared himself willing to be reconciled with the papacy.

Raymond's successes, however, had enabled the heretical Cathari to resume their activities. Warned by the local bishops, Pope Honorius III incited Louis VIII of France to conquer Languedoc. Raymond renewed his promises at the Council of Bourges, but was excommunicated and declared forfeit of his lands (Jan. 28, 1226). Abandoned by most of his subjects, he looked in vain for allies (negotiating especially with Henry III of England). Louis VIII died in November 1226, before the completion of his campaign, leaving France to his 12-year-old son Louis IX, but this stroke of fortune was not enough to restore Raymond's position. In April 1229 he did public penance in the Cathedral of Notre Dame in Paris and ratified the treaty concluded beforehand at Meaux.

By this treaty Raymond was to keep for his lifetime his lands in the diocese of Toulouse, with Agenais, Quercy, and part of Rouergue; if he left no son, all this was to pass at his death to Joan, daughter of his marriage to Sanchia of Aragon; and Joan was to marry Louis IX's brother Alphonse. Raymond also promised to fight against heresy and to make reparations of various sorts.

The defeated Raymond tried to recover some of his old power in Toulouse. He also resisted the excesses of the Inquisition in Languedoc. In 1242, in alliance with Henry III of England, he revolted against France; but Henry's defeat soon obliged him to submit (January 1243). Wanting a son, he married Margaret of La Marche-Lusignan (1243), then repudiated her in the vain hope of marrying Beatrice of Provence (1245).

In 1247, when Louis IX was preparing his crusade to the Holy Land, Raymond VII took the cross. He fell ill, however, and died at Millau on Sept. 27, 1249. At his own wish, he was buried at his mother's feet in the Abbey of Fontevault. (P. Wo.)

RAYMOND III (d. 1187), count of Tripoli and twice regent of the kingdom of Jerusalem, the ablest statesman of the Syrian Franks of his time, was the son and successor of Count Raymond II of Tripoli (assassinated 1152). His father was a great-grandson of the crusader Raymond IV of Toulouse; his mother was Hodierna, a daughter of King Baldwin II of Jerusalem. Taken prisoner in battle against the Muslim leader Nureddin in 1164, but released in 1172, Raymond III in 1174 successfully claimed the regency of the kingdom of Jerusalem, as the new king, Baldwin IV (q.v.), a minor and a leper, was his first cousin once removed. This regency ended on Baldwin's coming of age (1177); but Raymond continued to be active in the kingdom's affairs, as the spokesman of the older-established baronage against the "court party" of newcomers to Palestine, such as Raynald (q.v.) of Châtillon and Guy of Lusignan, second husband of Baldwin IV's sister Sibyl (see LUSIGNAN).

Raymond's rivals induced Baldwin IV to exile him for two years (1180–82); but the growing threat from Saladin on the one hand

and Guy's incompetence on the other finally led to the designation of the capable Raymond, early in 1184, as regent again, with the proviso that if the next king, Baldwin V (q.v.), should die prematurely, the succession to the crown should be determined by the Pope, the Holy Roman emperor, and the kings of France and England. As regent, Raymond obtained a truce for the kingdom from Saladin (q.v.). When Baldwin V died, however, in the summer of 1186, Sibyl and Guy took the throne in violation of the proviso of the regency. Refusing to acknowledge Guy, Raymond withdrew to Tiberias, a stronghold belonging to his wife, Eschiva of Bures, princess of Galilee; and when Saladin resumed war against the kingdom, Raymond maintained a separate truce. Finally the slaughter of some of Guy's supporters in the Galilee area by Muslims to whom Raymond had granted a safe-conduct impelled Raymond to reconcile himself with Guy. Despite Raymond's wise and disinterested protest, Guy advanced against Saladin and was disastrously defeated in the Battle of the Horns of Hattin (July 1187). Wounded in this battle, Raymond retired to die in Tripoli.

See M. W. Baldwin, *Raymond III of Tripoli* . . . (1936).

RAYMOND, HENRY JARVIS (1820–1869), the first editor of the *New York Times*, who did much to elevate the style and tone of newspapers in his day. Born near the village of Lima, Livingston County, N.Y., Jan. 24, 1820, and graduated from the University of Vermont (Burlington) in 1840, he taught, acted as correspondent for various papers, assisted Horace Greeley (q.v.) on the *New Yorker* and the *Tribune*, and served on the *Courier and Enquirer* before he obtained backing for a venture of his own. The first issue of the *New York Times* appeared Sept. 18, 1851. Of this journal Raymond was editor and chief proprietor until his death. Raymond was a member of the New York Assembly in 1850 and speaker in 1851 and again in 1862. He supported the views of the radical antislavery wing of the Whig Party in the north. His nomination over Greeley on the Whig ticket for lieutenant governor and his election in 1854 led to the final dissolution of the famous political alliance of Seward, Weed, and Greeley. He took a prominent part in the formation of the Republican Party, and drafted the famous "Address to the People" adopted by the Republican Convention that met in Pittsburgh, Pa., in February 1856. He was a member of the national House of Representatives in 1865–67. He retired from public life in 1867 and devoted his time to newspaper work until his death in New York City, June 18, 1869. He published several books, including a biography of Abraham Lincoln, which in substance originally appeared as *A History of the Administration of President Lincoln* (1864) and which with additions was republished under varying titles.

See A. Maverick, *Henry J. Raymond and the New York Press for Thirty Years* (1870); F. Brown, *Raymond of The Times* (1951).

RAYMOND, ROBERT RAYMOND, 1ST BARON (1673–1733), lord chief justice of England, a great judge, especially in criminal matters, whose reports, covering nearly 40 years, have a high reputation, was born on Dec. 20, 1673, the son of Sir Thomas Raymond, a judge under Charles II. He entered Gray's Inn in 1682 and was called to the bar in 1697. He soon acquired an extensive common-law practice, and in 1710 became solicitor general and member of parliament for Lymington, Hampshire, and was knighted. He lost office with the accession of George I in 1714, but by 1720 his Jacobite sympathies had been sufficiently forgiven for Lord Stanhope to make him attorney general. His position was uneasy, however, and in 1724 he surprisingly became a mere puisne judge of the king's bench. He at once displayed judicial powers of the highest order, and this, coupled with Walpole's admiration, led to his appointment as one of the lords commissioners of the great seal on Lord Macclesfield's disgrace in 1725. In the same year he succeeded Sir John Pratt as lord chief justice of the king's bench, an office which he held until his death on March 18, 1733; he had become a peer in 1731.

See Lord Campbell, *Lives of the Chief Justices* (1858).

(R. E. Mv.)

RAYNAL, GUILLAUME THOMAS (1713–1796), French writer and propagandist, widely read and very influential in his day, was an important precursor of the French Revolution. Born at Saint-Geniez in Aveyron, April 12, 1713, he was educated

at the Jesuit college at Rodez, and himself became a Jesuit. He taught at Pézenas, Clermont and Toulouse, left the Society of Jesus at about the age of 34 and went to Paris; he exercised minor ecclesiastical functions at Saint-Sulpice. Meanwhile he entered the world of letters and from 1747 to about 1752 was literary correspondent to the duchess Dorotea of Saxe-Gotha to whom he addressed his *Nouvelles littéraires*. His first major publications were *Histoire du stadthoudérat* (1747) and *Histoire du Parlement d'Angleterre* (1748), both hack work. In the first he appeared as an opponent of despotism; in the second, as an advocate of absolute monarchy, a discrepancy to be explained by the different orientation of French foreign policy in relation to Holland and to Great Britain. From 1750 to 1754 he edited the *Mercur de France*. This literary activity won for him a place in French society and he became a guest at the tables of Helvétius and D'Holbach and a friend of Montesquieu.

His most celebrated work was *Histoire philosophique et politique des établissements et du commerce des Européens dans les deux Indes*, first published in 1770 in six volumes, revised in 1774 and again, with changes of an outspoken and audacious character, in 1780. This was not his unaided work. Diderot, in particular, contributed extensively to it and Alexandre Deleyre, a disciple of Montesquieu, is reputedly responsible for the 19th book, which contains a general statement of political philosophy and is of more lasting interest than the rest. The whole work is a compendium of information and ideas on history, economics and politics, with an advanced anticlerical bias. Reprints were extremely numerous. The book fell foul of the Holy See in 1774, when it was placed on the Index, and of the *parlement* of Paris in 1781, when it was sentenced to be burned and the author was sent into exile. Raynal thereupon went first into Belgium, where he was the subject of many hostile lampoons, then into Prussia, where his reception at the hands of Frederick II was less cordial than he expected, and finally into Switzerland. In 1784 he was permitted to return to France, though not to Paris. He settled first at Toulon, then at Marseilles, where he entertained the youthful Napoleon, who read *Histoire philosophique*. His banishment from Paris was rescinded in 1790; he returned to the metropolis and engaged cautiously in political activity. He died at Chaillet on March 6, 1796.

See A. Feugère, *Un précurseur de la Révolution: l'abbé Raynal* (1922) and *Bibliographie critique de l'abbé Raynal* (1922); H. Wolpe, *Raynal et sa machine de guerre* (1957). (Rt. S.)

RAYNALD OF CHÂTILLON (d. 1187), one of the most energetic personalities among the crusaders, was a Frenchman from Châtillon-sur-Loing (the future Châtillon-Coligny, in Gâtinais) and was the brother of the seigneur de Gien. He left for the Holy Land in 1147 and put himself at the service first of Baldwin III of Jerusalem, then of Constance of Antioch, whose first husband, Raymond of Poitiers, was killed in 1149. Constance fell in love with Raynald and married him in 1153. One of their daughters, Agnes, later married Béla III of Hungary.

As prince of Antioch, Raynald showed himself courageous, but violent. He treated the patriarch, Aimery, with outrageous cruelty to extort money from him. At the instigation of the Byzantine emperor Manuel I Comnenus he attacked Armenian Cilicia; but subsequently he made peace with Thoros II of Cilicia and joined him in an invasion of Byzantine Cyprus. Manuel had his revenge in 1159, when Raynald was obliged to acknowledge himself as his vassal. In 1160, conducting a raid on the Muslims near Maras, Raynald was taken prisoner. He remained a captive till 1176.

Meanwhile Constance had died (1163), leaving Antioch to Bohemund III, the son of her first marriage. Raynald therefore returned to Jerusalem and, in 1177, married Stephanie, widow of the lord of Oultrejourdain (Transjordan east and south of the Dead Sea), thus becoming prince of Krak du Désert (Karak) and of Montréal. His new strongholds controlled the routes followed by Muslim traders; and twice, in times of truce, he attacked their richly laden caravans in transit (1181 and 1186). On each occasion Saladin (*q.v.*) requested the king of Jerusalem to make Raynald restore his plunder, and Raynald's refusal to comply cost the kingdom two wars against Saladin.

During the first war Raynald daringly launched five galleys on

the Red Sea, which not only blockaded the Muslims' port of Eilat (Elath) but harassed shipping, raided other Egyptian ports, and even threatened Mecca till an Egyptian fleet destroyed them (1182–83). On land, King Baldwin IV's army saved Krak from two sieges by Saladin (1183 and 1184).

Raynald played an important role in intrigues at the court of Jerusalem. It was thanks to his support that Queen Sibyl and her husband, Guy of Lusignan, were crowned in 1186, despite Count Raymond III (*q.v.*) of Tripoli. But when Guy asked Raynald to restore to Saladin the second caravan that he had waylaid, Raynald still refused, so that war broke out again. Taken prisoner in the great Battle of the Horns of Hattin (July 4, 1187), Raynald was conducted, with Guy, to Saladin's tent. Saladin, who had sworn to kill him, upbraided him for his truce-breaking in violation of his oath; but Raynald could have escaped death by becoming a Muslim. He refused to abjure his Christian faith, and so was beheaded on the spot, perhaps by Saladin himself.

RAYNAUD'S DISEASE, first described by P. Edouard Raynaud in 1862, is characterized by a reaction in a susceptible person following exposure to cold or emotional disturbance such as anger or fear. Typically there are three stages. During the first, the affected parts, most commonly the fingers or toes, less commonly the nose, cheeks or ears, become blanched or waxen and cold. They are relatively bloodless and if cut bleed little. This is caused by a spasm in the arterioles, the smallest arteries through which blood normally flows to the capillaries. In some patients the local colour changes to slate gray (the second stage). This persists while the stimulating factor continues and is associated with numbness, tingling and sometimes pain. Return to a warm environment or release from tension results in the relaxation of the arterioles and a flush of blood into the area together with a throbbing sensation, increased local warmth and intense redness, after which the part returns gradually to normal. The symptoms of this disease may occur frequently for years, with no evidence of serious damage; gangrene is extremely rare. The underlying cause is unknown. The onset usually occurs between the ages of 15 and 35 years; 90% of the cases are in females.

A similar phenomenon, Raynaud's syndrome, is known to be present in some patients in the early stages of arteriosclerosis and thromboangiitis obliterans, two diseases affecting the arteries of the extremities (*see ARTERIES, DISEASES OF*). The syndrome may also develop following repeated blows to a hand, as in the use of a pneumatic hammer or in the playing of handball, and has occurred in concert pianists and typists. Since it does not occur in all who are exposed, individual susceptibility must be assumed. Raynaud's syndrome is also associated with other diseases, such as scleroderma, a condition producing a hardening of the skin and sometimes the deeper tissues, and with some blood diseases such as cryoglobulinemia, in which the blood solidifies if reduced much below the usual body temperature.

Treatment for the classical Raynaud's disease is not specific. The patient should try to avoid exposure to stimulating factors. A warm climate is beneficial and it is advisable for the patient to wear warm gloves and socks and to avoid winter sports. Neurologic surgery has been widely used; it is more successful for Raynaud's disease of the feet than of the hands. Many drugs have been tried without much effect.

Treatment of Raynaud's syndrome secondary to some other condition must depend on the primary condition. If repetitive injury is responsible, the only recourse is to discontinue the activity causing it. The primary diseases mentioned above must be treated. In addition cold, being an aggravating factor, must be avoided.

See I. S. Wright, *Vascular Disease in Clinical Practice*, 2nd ed. (1954). (I. S. W.)

RAYNOUARD, FRANÇOIS JUSTE MARIE (1761–1836), French dramatist and Romance philologist who also played some part in the politics of the Revolutionary and Napoleonic period, was born at Brignoles in Provence, Sept. 18, 1761, and

educated for a legal career. Sent as deputy to the legislative assembly in Paris. (1791), he was imprisoned on the fall of the Girondins (1793) but released in the Thermidorian reaction (1794). His first play *Caton d'Utique* was then published. After practising as a lawyer at Draguignan, he returned to Paris in 1803. His second play, *Les Templiers* (1805), was a great success in the theatre. He was made a member of the Corps Législatif (1806) and of the Académie Française (1807). His next play, *Les États de Blois, ou la mort du duc de Guise* (1810), offended Napoleon and was banned; his later tragedies attracted little notice. After Waterloo, Raynouard abandoned politics, despite the protests of constituents in the Var département, and devoted himself to the study of the language and literature of the troubadours. His major works were *Choix des poésies originales des troubadours*, 6 vol. (1816–21; vol. 6 was also published separately as *Grammaire comparée des langues de l'Europe latine dans leurs rapports avec la langue des troubadours*, 1822) and the posthumous *Lexique roman*, 6 vol. (1838–44). He was a member of the Académie des Inscriptions from 1816.

Raynouard died at Passy on Oct. 27, 1836.

RAYON: see FIBRE.

RAYONNANT STYLE, in architecture, the fully developed French Gothic style (see GOTHIC ARCHITECTURE) of the latter half of the 13th and the first three-quarters of the 14th century. It is characterized by a complete mastery of the structural ideas of the Gothic vaulted church; great skill in stone-cutting; the elimination of wall surface; the reduction in area of all supports to the minimum; thorough development and lavish use of bar tracery (*q.v.*) based on geometric forms; reduction in size and importance of the triforium gallery; and a general attempt to accent all vertical lines. In carved ornament the spherical crocket of the earlier Gothic was replaced by a fully opened, upturned leaf and naturalistic foliage-decorated capitals, string courses, and the like.

"Rayonnant" pertains to the radiating tracery of the rose windows, a single, although characteristic, detail; the term has been nearly abandoned, even in France. Marcel Aubert in Robert de Lasteyrie's posthumous work, *L'Architecture Religieuse en France à l'Époque Gothique*, vol. ii, p. 5, calls the style from 1140 to 1200 *le gothique primitif* and that of the years 1200 to 1400 simply *gothique*.

Characteristic examples are: Sainte-Chapelle, Paris (1243–48); the choir of Amiens Cathedral (1258–69); additions to the transepts of Notre Dame in Paris (1258–1315); Saint-Urbain in Troyes (1262–76); Portail des Libraires at Rouen Cathedral (1280); and the choir of the abbey church of Saint-Ouen at Rouen (1318). Chronologically, this phase of French Gothic corresponds to the Decorated period (*q.v.*) in England and the High Gothic style in Germany. In France it was followed by the Flamboyant style (*q.v.*). (P. F.)

RAZI, AL- (FAKHR AL-DIN ABU 'ABDALLAH MOHAMMED IBN 'UMAR IBN AL-HUSAIN AL-RAZI) (1149–1209), Muslim theologian and scholar, was born the son of a preacher at Ray (Rhagae), near the modern Teheran. After devoting himself to alchemy in his youth, he studied theology and philosophy at Ray and Maragha. In law he followed the school of al-Shafi'i (*q.v.*), on whose merits he composed a celebrated book; in theology that of al-Ash'ari (*q.v.*). Although he could not come to terms with the anti-intellectualism of the mystics, he was recognized as an authority on the mystic life as well as on scholastic theology and the law. As a student of tradition, however, he was considered weak. His contemporaries saw in him above all the defender of orthodoxy against dissenters and heretics. During an extensive journey to Khwarizm (Khorezm) and Transoxiana he preached (in Arabic and Persian) against the local sectarians and more particularly against the philosophical school of the Mu'tazilites, who, in the end, compelled him to withdraw to his birthplace. Subsequently, he found honour at the court of Shihab ud-Din Ghuri and especially in the entourage of the Khwarizmshah Ala ud-Din Mohammed, whom he followed to Khurasan. Later he settled in Herat, where he died, as some would have it, poisoned by one of the sects which he had combated.

His greatest work, *Mafatih al-Ghaib* ("Keys of the Hidden"), an extensive commentary on the Koran, has been printed at various times in Cairo and Istanbul. Razi studied the Koran also from the point of view of its style and examined the rare expressions in the holy book. Some of his dogmatic and legal writings continue to enjoy a high reputation, as do his contributions to philosophy. His dogmatic position was analyzed by Schmölders in his *Essai sur les écoles philosophiques chez les Arabes* (1842). His disputations with the Mu'tazilites were studied by P. Kraus in *Islamic Culture* (1938) and the *Bulletin de l'Institut Égyptien* (1939).

For a list of Razi's works see C. Brockelmann, *Geschichte der arabischen Literatur*, 2nd ed., vol. i, pp. 666–669 (1943–49); and M. Schreiner, in *Zeitschrift der deutschen morgenländischen Gesellschaft*, vol. lii. The most extensive source for his biography is Taj ad-Din Subki (d. 1370), *Tabaqat ash-Shafi'iyya al-kubra* (1323–24 and 1905–06). (G. E. v. G.)

RAZIN, STENKA (STEPAN TIMOFEEVICH) (d. 1671), was the leader of a Cossack and peasant rebellion on Russia's south-eastern frontier between 1667 and 1671. Razin was a Don Cossack born in a well-to-do family in the village Zimoveiskaya on the upper Don. Little is known of his youth. The constant stream of runaway serfs from Russia and Poland to the Don Cossack area where there was neither land nor place for them in the settled, prosperous Cossack communities caused much tension in Razin's home region during that time.

STENKA RAZIN, DETAIL OF AN ENGRAVING FROM "A RELATION CONCERNING THE PARTICULARS OF THE REBELLION LATELY RAISED IN MUSCOVY BY STENKA RAZIN," LONDON, 1672

them. The following year he defeated a fleet which the shah of Persia had sent against him.

Razin then stood at the pinnacle of his brief career. His ventures had brought him fame among the Cossacks and much wealth; even the Russian authorities, pleased by his triumph over the Persians, tended for the time being to ignore his crimes.

In early 1670, having returned to the Don, Razin suddenly announced his intention of marching with his force of about 7,000 Cossacks against the tsarist fortress-cities on the Volga. Aided by the treachery of sympathizers within these cities, he seized Tsaritsyn (Volgograd) and Astrakhan. In both towns Razin and his men engaged in drunken orgies and perpetrated savage atrocities; he also abolished local government, replacing it with Cossack institutions of self-rule. Encouraged by his successes and by intelligence which indicated wide support from the peasantry and lower urban inhabitants, he decided to continue his advance up the Volga, inciting the population along the way to merciless class war. He captured Saratov, and then moved his forces, which had swollen to the number of 20,000, to the walls of Simbirsk (Ulyanovsk).

The rebellion spread all over the Volga region, the lands adjoining the Don and Donets rivers, and even to some of the inner provinces of the Russian state. The tsarist government, alarmed by the spread of anarchy, mustered a sizable army which included some of its best Western-style regiments. Headed by Prince Yuri Baryatinski this army came to the aid of beleaguered Simbirsk,

and in October 1670 inflicted a decisive defeat on Razin's undisciplined troops. Razin fled to the Don where on April 24 (new style; 14, old style), 1671, he was captured by Cossacks loyal to Moscow, and turned over to the authorities. Razin was brought to the capital, tortured, and publicly executed on June 16 (N.S.; 6 O.S.), 1671. The rebellion was suppressed shortly after his capture.

The Razin uprising combined two distinct forces, Cossacks and peasants. The former were inspired by anarchist ideals, the latter by hatred of serfdom which had been finally legalized in 1649.

While the element of social protest was present in the rebellion, the tone was set by the anarchic element whose aim was loot and destruction. For this reason, most Russian historians tend to relegate Razin to a minor place in their narrative. In Russian folklore, on the other hand, Razin is a popular hero, the incarnation of a free man who triumphs alike over society and nature.

END OF VOLUME EIGHTEEN

Encyclopædia Britannica;

OR, A DICTIONARY OF ARTS and SCIENCES, COMPILED UPON A NEW PLAN.

IN WHICH
The different SCIENCES and ARTS are digested into
distinct Treatises or Systems;
AND
The various TECHNICAL Terms, &c. are explained as they occur
in the text of the Alphabet.

ILLUSTRATED WITH ONE HUNDRED AND SIXTY COPPERPLATES.
By a SOCIETY OF GENTLEMEN in SCOTLAND.

IN THREE VOLUMES.
VOL. I.

EDINBURGH:
Printed by A. DILL and C. MACRAE,
And sold by G. & J. MACRAE, at the Printing-office, West-Edinburgh.
MDCCCLXI.

CONIC SECTIONS.
CONIC SECTIONS are those which are formed by the intersection of a cone and a plane. They are of three kinds: the circle, the ellipse, and the hyperbola. The circle is formed when the plane is perpendicular to the axis of the cone. The ellipse is formed when the plane is oblique to the axis. The hyperbola is formed when the plane is parallel to the axis.
